Early liver transplantation can improve survival in familial amyloid polyneuropathy. For transplant recipients with a modified body mass index (which is multiplied by serum albumin level) greater than 600 $kg/m^2 \cdot L^{-1}$, improved survival has been noted compared with historical control participants without transplantation. It is important for these patients to undergo transplantation when their nutritional status is good.[122] Domino liver transplantation, in which the recipient's liver is in turn given to another recipient, has been used for patients with familial amyloidosis, in one reported case resulting in the transmission of amyloidosis.[123] The authors have seen a patient with hepatic failure from hepatitis C develop amyloid neuropathy 7 years after receiving the liver of a patient with TTR amyloidosis. She was retransplanted within 3 months of histologic proof of amyloidosis.

In summary, any patient with amyloidosis who lacks a monoclonal protein in the serum and urine and does not have a plasma cell dyscrasia should be evaluated for the presence of localized, secondary, senile, or familial amyloidosis. Rarely, a patient with amyloidosis and a monoclonal gammopathy can also have a nonimmunoglobulin form of amyloidosis, and immunohistochemical staining or preferably mass spectroscopic analysis of the amyloid deposits is warranted to exclude this possibility.

CLINICAL PRESENTATION OF PRIMARY AMYLOIDOSIS

A distinct male predominance in amyloidosis has been noted for more than 40 years. In Mayo Clinic patients with AL, 67% are male; males comprise 52% of all MM patients. The median age of patients with amyloidosis seen at Mayo Clinic is 67 years. The median age of patients with AL from Olmsted County, however, is 73 years, which may reflect referral bias of younger patients.

When patients are classified by a dominant organ manifestation, cardiac amyloidosis is the most common and is seen in 37.4% of patients (Fig. 87-10). Overt congestive heart failure is found in half of patients with demonstrable cardiac amyloidosis. The others have manifestations that include fatigue, arrhythmia, or syncope. The widespread use of echocardiography has increased the recognition of cardiac amyloidosis.[124] Dominant renal amyloidosis is seen in 27.8% of patients. The most common manifestation is nephrotic-range proteinuria (albuminuria). Amyloid peripheral neuropathy is seen in 15.3%. Hepatomegaly is found in 17.7% of amyloidosis patients, but liver amyloidosis presenting as the dominant manifestation is seen in only 4.6%. Gastrointestinal (GI) tract amyloidosis manifested by intestinal bleeding, pseudo-obstruction, or diarrhea is seen in 7.1% of patients, and the other patients (7.8%) have a heterogeneous mix of soft tissue, vascular, tongue, periarticular, and pulmonary interstitial amyloidosis.

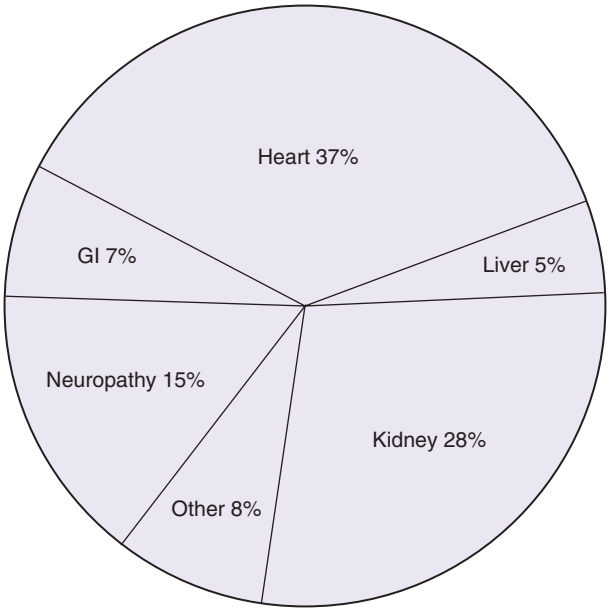

Figure 87-10 DISTRIBUTION OF DOMINANT SYNDROMES IN PATIENTS WITH AMYLOIDOSIS. *GI,* Gastrointestinal.

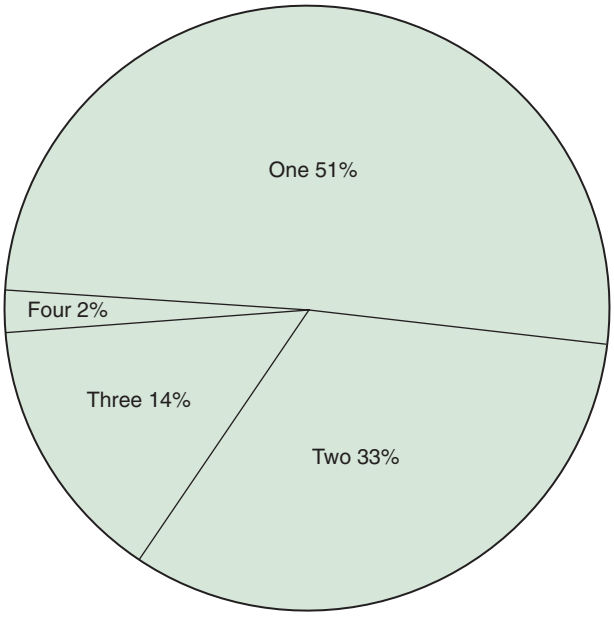

Figure 87-11 NUMBER OF ORGANS INVOLVED AT PRESENTATION IN MAYO CLINIC PATIENTS WITH AMYLOIDOSIS.

In the authors' patient population,[125] 49% presented with two or more organs involved (Fig. 87-11). In assigning a dominant organ of involvement, the designation is occasionally arbitrary because it is often difficult to distinguish which of the organs is responsible for the presenting symptoms.

If presentation with purpura alone is excluded, only 2.3% of patients presented with significant bleeding, 16.4% had carpal tunnel syndrome, and 19.6% had clinically overt congestive heart failure.[126] Symptoms included edema in 44.8% and fatigue in 46.4%. Nephrotic-range proteinuria was seen in 21%, orthostatic hypotension in 12%, lower extremity paresthesias in 34.9%, and weight loss in 51.7%. Anemia is uncommon in AL; 90% of patients have a hemoglobin value greater than 10 g/dL.[126] Only 1.5% of patients had a hemoglobin value less than 8 g/dL, and this was usually a sign of active intestinal tract hemorrhage or the anemia of renal failure. The median platelet count was 257×10^9/L; only 5.5% had a platelet count greater than 500×10^9/L. Thrombocytosis usually is seen with hepatic amyloidosis and hyposplenism.

A serum creatinine concentration greater than 2 mg/dL is present in 13.6% of patients at presentation.[126] An alkaline phosphatase concentration of two times the institutional normal value, which reflects hepatic involvement, is present in 6.7%. The median number of BM plasma cells is 7% (range, 1%-30%) (see Fig. 87-6); 12% of patients with AL have more than 20% plasma cells in the BM without any other signs of MM. The median 24-hour urine protein loss for all patients was 790 mg/24 hr (see Fig. 87-5). The monoclonal light chain is λ in 70%, κ in 19%, and no monoclonal protein is found in 11%. However, when the immunoglobulin light chain levels and ratios are measured, then fewer than 1% of systemic AL patients fail to have an identifiable light-chain disorder. When an immunoglobulin (Ig) heavy chain was detectable in the serum, it was IgG in 58%, IgA in 10%, and IgM in 8% (see Fig. 87-4). It is important to remember that amyloidosis is associated with IgM monoclonal gammopathies.[127] Waldenström macroglobulinemia has also been reported to be associated with amyloid arthropathy presenting as bilateral symmetric polyarthritis.[128a] Rarely, Waldenström macroglobulinemia is associated with AA amyloidosis, although most patients with macroglobulinemia developing amyloidosis have AL.[128b,128c]

Echocardiographic findings in the entire patient population demonstrate a median septal thickness of 14 mm.[126] The septal thickness is less than 15 mm in 53% and 15 mm or greater in 47%, reflecting a high proportion of patients with cardiac amyloidosis at diagnosis. The median survival of all patients is approximately 12 months. The 2- and 5-year survival rates are 33.6% and 15%, respectively. Variables important in survival prediction include the patient's performance status on the Eastern Cooperative Oncology Group scale, the presence of heart involvement as the dominant syndrome, and the involvement of two or more organs at presentation. Survival in amyloidosis has been steadily improving over the decades.[128d]

Kidney

When free monoclonal light chains are found in the urine, the differential diagnosis of the proteinuria is cryoglobulinemia,[129] amyloidosis, light-chain deposition disease,[130,131] and myeloma cast nephropathy. Immunofixation of the urine is important in the diagnostic evaluation whenever protein is present. Renal involvement is seen in 28% of Mayo Clinic patients,[126] but in the Italian Intergroup, the frequency of renal involvement was nearly 50%.[132] In nondiabetic adults with nephrotic syndrome, amyloid is seen in 12% of biopsies. Survival is associated with the serum creatinine value at diagnosis.[133] The median survival of patients with a creatinine value less than and greater than 1.3 mg/dL was 25.6 and 15 months, respectively. Patients with increased protein excretion do not have shorter survival but do have a shorter time to the development of end-stage renal disease.[134] Fewer than 5% of patients with AL have urinary protein loss less than 150 mg/day. Two-thirds of patients have a light chain detectable in the urine, and two-thirds a detectable light chain in the serum. In AL patients with greater than 1 g of proteinuria, a light chain can be found in as many as 86%. The ratio of κ to λ light chains in patients with nephrotic syndrome is one to five. The median urinary protein loss in κ light-chain amyloidosis is 1.1 g/day; in λ light-chain amyloidosis, it is 4.6 g/day. There is no difference in the frequency of renal insufficiency in κ and λ light-chain amyloidosis.

Long-standing proteinuria results in hypoalbuminemia, which leads to decreased intravascular oncotic pressure. The clinical end result is transudation of fluid into the extracellular space with refractory edema. The use of diuretics can aggravate intravascular volume contraction and hypotension and reduces renal blood flow. In patients with advanced anasarca, bilateral catheter embolization of the renal arteries has been used.[135] Recently, the authors have also placed clips on the ureters laparoscopically to manage a patient with intractable nephrotic syndrome. The continuous loss of protein into the urine produces tubular atrophy and damage. The median time from the

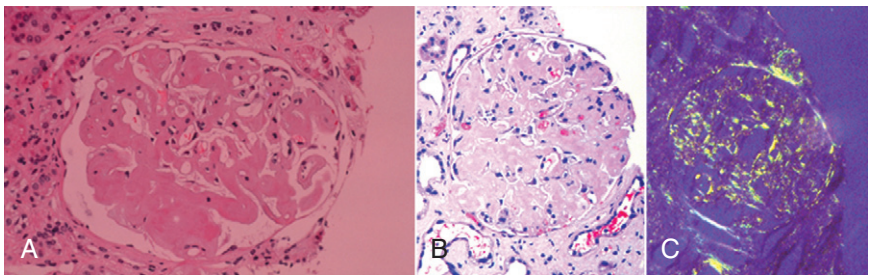

Figure 87-12 A, Amyloid deposits in the glomerulus. Note the amorphous nature that could easily be confused with hyalin degeneration (hematoxylin and eosin; original magnification, ×100). **B,** A second case showing amyloid deposits (×100); **C,** Congo red stain with "apple-green" birefringence (×100).

diagnosis of AL nephrotic syndrome to dialysis is 14 months; the median survival from the start of dialysis in AL patients is 8 months. The cause of death in most patients is the development of cardiac amyloidosis. The authors have not recognized a difference in outcome between patients undergoing hemodialysis and peritoneal dialysis; the 1-year survival rate is 68% after initiation of dialysis. The most important extrarenal complications of AL are heart failure, heart arrhythmias, and hypotension. Dialysis is regularly complicated by hypotension.

The amount of proteinuria is poorly correlated with the extent of amyloid deposits on biopsy (Fig. 87-12). Most patients with AL have normal-sized kidneys by ultrasonography. The urinary sediment shows fat but no casts or red blood cells. In a study of 118 patients with monoclonal gammopathies, 30% of those having a renal biopsy had AL.[136] The median survival time in the group was 24 months, with death largely caused by cardiac amyloidosis. Predictors of survival included age younger than 70 years and high serum calcium and creatinine concentrations at presentation. It is rare for renal amyloidosis to develop if it is not present at diagnosis. The authors have seen four patients in whom nephrotic-range proteinuria developed after cardiac transplantation for amyloidosis. Presumably, in the past, these patients would not have survived long enough for renal amyloidosis to develop.

The cause of the proteinuria in AL is amyloid deposits disrupting the glomerular basement membrane. Immunotactoid (fibrillary) glomerulopathy is a fibrillar deposition in the kidney that can be confused with AL.[137] On electron microscopy, the fibrils of fibrillary glomerulopathy are twice the width of amyloid fibrils, and the deposits do not stain with Congo red. Light-chain deposition disease (Randall type) represents the deposition of nonamyloid immunoglobulin light chains in a granular fashion on the tubular or glomerular basement membrane.[138a] It can produce nephrotic syndrome and renal failure. Amyloidosis and light-chain deposition disease have been reported in the same patient. Light-, light and heavy–, and heavy-chain deposition diseases display essentially similar characteristics, such as involvement of multiple organs, prominent renal involvement with severe renal failure, diabetes-like nodular glomerulosclerosis, marked thickening of tubular basement membranes, and monotypic deposits of Ig light chains (mostly κ) or heavy chains (mostly γ) that feature a non-organized granular, electron-dense appearance by electron microscopy.[138b]

Few reports exist of renal transplantation for AL. In a report on 12 patients, two of whom had AL, four were alive at 2 years, and in two of these four, the renal biopsy showed recurrent amyloid.[139] In another report, 11 patients received transplants, and three showed recurrent amyloid deposits in the allograft at 11, 28, and 37 months.[140] In 45 patients with amyloidosis who received a renal transplant, the 3-year survival rate was 51%, which is inferior to the outcome of renal transplantation for primary renal disease.[141] The estimate for recurrent amyloidosis in a recipient of a renal transplant is approximately 20% at 1 year. On scintigraphy, uptake of radiolabeled serum amyloid was seen in four of 10 renal transplant recipients. Of 22 patients with renal amyloidosis, seven had adrenal insufficiency, and four died of hypoadrenalism.

The authors performed living donor kidney transplantation followed by autologous stem cell transplantation (SCT) for AL patients with end-stage renal disease.[142] Two patients had complications and died 3 and 10 months later. Two patients had development of subclinical acute cellular rejection, and one patient had acute rejection, all reversible. Six patients had successful stem cell harvest, and five underwent SCT with good engraftment. Renal function stabilized after SCT in four and was decreased in one. The feasibility of donor kidney transplant with an autologous SCT for carefully selected patients has been established.[142] It is unclear whether SCT should precede or follow kidney transplantation.[143a] In the United Kingdom, renal transplants were performed in 22 patients with AL. One- and 5-year patient survival rates were 95% and 67% among kidney recipients, respectively. No renal graft failed because of recurrent amyloid during median (range) follow-up of 4.8 (0.2-13.3) years.[143b]

Heart

The extent of cardiac amyloid is the most important factor determining outcome in AL. Patients present with infiltrative cardiomyopathy that leads to restricted ventricular filling and may present with disabling fatigue and unexplained weight loss. These patients have early diastolic dysfunction and no systolic dysfunction.[144] Chest radiography does not show cardiomegaly or pulmonary vascular redistribution. The ejection fraction is preserved on echocardiography. As a result of poor diastolic filling and normal contractility, the ejection fraction is normal, but end-diastolic volume is decreased as a result of poor filling, and this results in low cardiac output.[145] Electrocardiography (ECG) typically shows low voltage, which is frequently overlooked.[146] Patients can be misdiagnosed as having ischemic heart disease because of the pseudoinfarction pattern seen in amyloidosis, with loss of the R wave in leads V1 through V3. Coronary arteriography is commonly performed during evaluation and is invariably normal.[147] Echocardiography shows thickening as a result of infiltration, but this can easily be misinterpreted as concentric left ventricular hypertrophy[148] or asymmetric septal hypertrophy (Fig. 87-13).

A patient with diastolic heart failure or restrictive hemodynamics should be evaluated for the presence of a monoclonal protein in the serum or urine.[149] The noncompliant left ventricle caused by infiltration is referred to as the "stiff heart."[150] There is minimal effect on systolic function, and the ejection fraction is preserved until late in the course of the disease. Echocardiography can be misleading owing to the normal ejection fraction and a lack of focal or segmental wall motion abnormalities.[151] The infiltration of the myocardial wall does result in thickening, but ECG does not show the voltage changes of ventricular hypertrophy. Instead, it shows low voltage or the pseudoinfarction pattern.

Doppler studies are required to assess myocardial function in AL because Doppler echocardiography best demonstrates restriction to inflow during diastole.[152] The Doppler filling patterns closely relate to the extent of amyloid infiltration. Patients with early cardiac amyloidosis show abnormal relaxation. Patients with advanced cardiac AL show a short deceleration time consistent with restrictive physiology. The combination of decreased fractional shortening of less than 20% and a mean left ventricular wall thickness of 15 mm is associated with a median survival time of only 4 months. A short deceleration time on Doppler echocardiography indicates restrictive physiology, and these patients have shortened survival times compared with patients with deceleration times exceeding 150 msec.

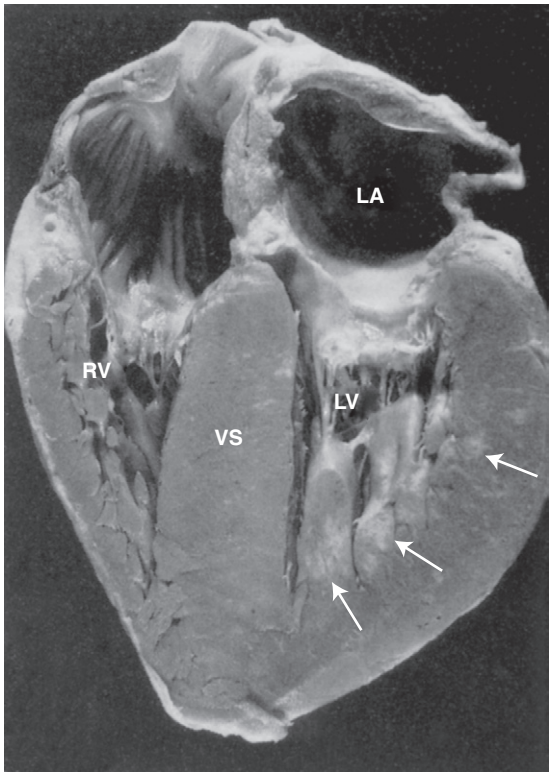

Figure 87-13 AUTOPSY SPECIMEN OF CARDIAC AMYLOIDOSIS. *Arrows* indicate the white deposits of amyloid that Rokitansky thought were "lardaceous." *LA,* Left atrium; *LV,* left ventricle; *RV,* right ventricle; *VS,* ventricular septum.

The recent introduction of echocardiographic strain imaging demonstrated its ability to show functional abnormalities before any morphologic echocardiographic abnormalities were present.[153] When combined with tissue Doppler imaging, cardiac involvement can be detected in early stages.[153a] However, myocardial strain could not differentiate hypertrophic from an infiltrative etiology of a thickened septum.[153b] Magnetic resonance imaging has also been used for early detection of cardiac amyloidosis. The combination of widespread myocardial enhancement on delayed postcontrast inversion recovery T1-weighted images with features of restrictive cardiac disease is highly suggestive.[154a] Late gadolinium enhancement is common in cardiac amyloid and detects interstitial expansion from amyloid deposition. Global transmural or subendocardial late gadolinium enhancement is most common, but suboptimal myocardial nulling and focal patchy late gadolinium enhancement are also observed. LGE-CMR may detect early cardiac abnormalities in patients with amyloidosis with normal left ventricular thickness.[154b]

Sudden death is a well-recognized complication of cardiac amyloidosis.[155] Digoxin has been associated with a risk of sudden death in AL. Digoxin provides rate control in the presence of atrial fibrillation but is unlikely to improve myocardial performance because systolic function is so well preserved in AL.[156] The mainstay of supportive care in cardiac AL is the use of diuretics.[157,158] The presence of orthostatic hypotension and intravascular volume contraction can make diuretic therapy difficult and may cause syncope or an increase in the creatinine value. Pacemaker implantation is commonly required in patients with cardiac amyloidosis and syncope. The use of angiotensin-converting enzyme inhibitors, a standard for the management of heart failure, has an uncertain role in AL. The high frequency of hypotension associated with angiotensin-converting enzyme inhibitors limits their value in AL. The use of implantable cardioverter-defibrillator therapy has been reported. A defibrillator cannot consistently prevent cardiac death from amyloidosis.[159,160a] Sustained ventricular arrhythmias (both monomorphic ventricular tachycardia and ventricular fibrillation) is a mechanism of sudden death in patients with cardiac amyloidosis and suggests that implantable cardiac defibrillator (ICD) therapy may be appropriate in selected patients.[160b]

Of 204 patients with AL seen at the Mayo Clinic, the median septal thickness was 14 mm.[161] The most common echocardiographic features are a thickened right ventricular wall, interventricular septum, and left ventricular free wall. Typically, the left ventricular cavity size is decreased. Cardiac involvement is present on echocardiography in 41% of patients at presentation; overt congestive heart failure is present in 20%. If the interventricular septal thickness is 15 mm or greater, the median survival time is less than 1 year. If the septal thickness is less than 15 mm, the median survival time can approach 4 years. Exercise-induced syncope has been associated with a median survival time of 2 months and is presumed due to complex ventricular arrhythmias.[162] Any patient presenting with symptoms of a cardiomyopathy that does not have a clear-cut ischemic etiology should have immunofixation analysis of the serum and urine and measurement of the free light-chain level performed.

The pseudoinfarction pattern seen on ECG may misdirect the evaluation toward coronary disease. Low voltage is seen on ECG in nearly two-thirds of patients with cardiac AL.[163] Cardiac amyloidosis is characterized by atrial systolic failure and dilatation of the right ventricle. Thickening of the mitral and tricuspid valves is common and is an important clue to the diagnosis. Doppler examination regularly demonstrates clinically insignificant valvular regurgitation.[164] Atrioventricular pacing does not improve cardiac hemodynamics.

Restrictive cardiomyopathy can be confused with pericardial disease causing restriction.[165] Little clinical benefit has been reported from pericardiectomy in patients with AL. An endomyocardial biopsy establishes the diagnosis of AL 100% of the time if at least three biopsy specimens are obtained.[166] Owing to poor contractility, the development of thrombi in the ventricular chambers is common. These can be sources of cardiac emboli resulting in stroke or arterial insufficiency of a lower extremity.[167a] Intracardiac thrombosis occurs frequently in cardiac amyloid patients, especially in those with atrial fibrillation. The risk for thrombosis was increased if the left ventricular diastolic dysfunction and atrial mechanical dysfunction were present. Anticoagulation therapy appears protective. Timely screening in high-risk patients may allow early detection of an intracardiac thrombus. Anticoagulation should be carefully considered.[167b] Atrial standstill in amyloidosis is an indication for long-standing anticoagulation therapy. Rarely, patients can have occlusive deposition of amyloid in small-caliber coronary arterioles. These patients can have ischemic symptoms, including exertional angina and true myocardial infarction.[32] Large-caliber coronary arteries show no abnormalities on angiography. Exercise testing regularly confirms ischemia, but the diagnosis is difficult to establish premortem.

The authors have seen 11 patients who presented with angina or unstable coronary syndromes.[31] Low voltage on ECG was seen in only two, and the median time from symptomatic angina to death was 18 months. Most diagnoses of cardiac AL with coronary artery occlusion were made at autopsy. Obstructive coronary amyloidosis is present in 66% of patients with cardiac involvement. None of these patients have obstruction of epicardial coronary arteries. Myocardial ischemia affects 25% of patients with obstructive intramural coronary amyloidosis. These patients present with ischemia and have normal angiographic studies but have small arteriolar amyloid disease.[31]

All patients with cardiac amyloidosis do not have AL. Familial forms of amyloid cardiomyopathy caused by mutations at position 122 of TTR are commonly seen in older African American men. These patients do not have a monoclonal protein in serum or urine. Senile cardiac amyloidosis is associated with cardiac deposition of wild-type TTR.[168] The echocardiographic features of these forms of cardiac amyloidosis are indistinguishable, and all three show Congo red–positive deposits. One-fourth of patients older than 90 years have amyloid deposits in the heart. Failure to find an immunoglobulin light chain in the serum or urine should redirect the evaluation toward non–light-chain forms of amyloid. Clues to senile systemic

amyloidosis include male sex, advanced age, pronounced thickening of the interventricular septum (frequently >20 mm), and TTR immunostaining or protein identification by mass spectroscopy of the endomyocardial biopsy.

Liver

Hepatomegaly is found by physical examination in one-fourth of patients and may be caused by cardiac failure and hepatic congestion. Symptomatic hepatic involvement is present in 16% of patients. The most common clinical presentations are unexplained hepatomegaly accompanied by an increase in serum alkaline phosphatase. There is high concordance between hepatic and renal involvement, and if the liver is involved, the kidney is the next most commonly involved organ. Half of patients with hepatic amyloidosis spill greater than 1 g of protein in the urine over 24 hours. Proteinuria in a patient with hepatomegaly and an increased alkaline phosphatase value is an important clinical clue to the diagnosis of AL.[169]

Four clinical clues permit the prebiopsy recognition of hepatic amyloidosis: (1) presence of proteinuria; (2) monoclonal protein in the serum or urine; (3) Howell-Jolly bodies in the peripheral blood, which reflect splenic replacement with amyloid; and (4) hepatomegaly out of proportion to the degree of abnormality of liver function tests. Most patients have only an increased alkaline phosphatase value. The concentrations of aspartate aminotransferase and alanine aminotransferase are typically less than twice normal at diagnosis. The bilirubin value is normal. The finding of an increased bilirubin value in a patient with hepatic amyloidosis is usually a preterminal finding.[170] Rarely, hepatic amyloidosis occurs with splenic rupture with intraabdominal hemorrhage and, rarely, hepatic rupture.[171] Hepatic rupture has been diagnosed in AL, with computed tomography of the abdomen demonstrating a subcapsular hematoma.[172] At the time of diagnosis of hepatic amyloidosis, the median liver span is 7 cm below the right costal margin; 50% of patients have a span between 5 and 9 cm.[173]

Ten percent of patients with hepatic amyloidosis on liver biopsy do not have palpable hepatomegaly and are diagnosed because of an unexplained increase in alkaline phosphatase.[173] Splenomegaly is seen in 11% of these patients and nephrotic-range proteinuria in 36%. At diagnosis, the median elevation of the alkaline phosphatase value is 2.3 times the upper limit of normal. There is no difference in the ratio of κ to λ light chains in hepatic amyloidosis compared with other forms of amyloidosis.

Liver biopsy is not a high-risk procedure in these patients, and although reports of hepatic rupture have appeared in the literature, the bleeding incidence is 4%, with a transfusion being needed in 2%. The authors recently reported their updated experience with hepatic amyloidosis.[174] Seventy-two percent of patients had involuntary weight loss leading to an evaluation for occult malignancy. Clinicians considered amyloidosis in the differential diagnosis in only 26% before liver biopsy. Predictors of a poor prognosis included heart failure, an elevated bilirubin level, and thrombocythemia.[174]

Cholestatic jaundice is a preterminal finding.[175] Portal hypertension with varices and GI tract bleeding is rarely seen.[176] Presumably, patients succumb to the effects of extrahepatic amyloid deposits before portal hypertension can develop. Ascites is commonly seen but is usually a consequence of concomitant nephrotic syndrome with hypoalbuminemia or of severe congestive heart failure rather than portal hypertension.[177] Liver biopsy shows perisinusoidal and portal deposition in most patients. Vascular involvement of the portal triads is common but not clinically important. The median survival time after diagnosis was 8.5 months.

Radionuclide scintigraphy in amyloidosis is nonspecific, showing irregular distribution of the radionuclide[178] and absence of splenic uptake.[179] This form of imaging is not clinically useful. Angiography is also nonspecific, demonstrating luminal irregularity and abrupt changes in the caliber of the branches of the hepatic artery.[180] The hepatic artery is presumed to be compressed by sinusoidal amyloid deposition. Although liver biopsy is a safe technique, biopsy of the subcutaneous fat or the BM yields a correct diagnosis in 85% of patients, so only a few patients should be subjected to percutaneous liver biopsy.

Patients with hepatic AL have been treated with transjugular intrahepatic portal systemic shunting.[181] This can decrease portal pressures, ascites, and hydrothorax. In one patient, bilateral nephrectomy for uncontrolled nephrotic syndrome resulted in an improvement in liver function and normalization of hyperbilirubinemia.[182] The presence of hepatic involvement in amyloidosis does not adversely affect survival on multivariate statistical analysis. As noted, hepatomegaly may be from causes other than direct infiltration of the organ. In one report, hepatomegaly was caused by passive congestion of the liver without hepatic amyloid deposits in three of nine patients.[183] A second study found that 20% of patients with amyloidosis and palpable hepatomegaly did not have parenchymal amyloid deposits at autopsy.[184]

The presence of hyposplenism on the peripheral blood film is highly specific for a diagnosis of amyloidosis. Conversely, hyposplenism is not a sensitive indicator of splenic involvement.[185] In one report, 12 patients with diffuse splenic involvement at autopsy did not have peripheral blood film evidence of hyposplenism.[185] Technetium scanning can indicate a decrease in splenic blood flow, but this correlates poorly with the findings on the peripheral blood film.

In summary, the cardinal features of hepatic AL are (1) hepatomegaly with increased concentration of alkaline phosphatase and minimal change in aspartate and alanine aminotransferases, (2) proteinuria, (3) a monoclonal light chain in the serum or urine, and (4) hyposplenism on peripheral blood film or technetium scanning.

Gastrointestinal Tract

Anatomic deposits of amyloid are seen in the GI tracts of most patients by screening rectal biopsy or upper endoscopy. These deposits tend to be vascular, are in the submucosa (see Fig. 87-14, *A* and *B*), and are not associated with symptoms or clinical signs. Fewer than 5% of patients with AL present with symptoms referable to the GI tract. The presence of anorexia and weight loss generally is not associated with substantial GI tract deposits, and the cause of the weight loss is unrelated. Malabsorption defined by steatorrhea or a low serum carotene value is seen in fewer than 5% of amyloidosis patients. The symptoms of advanced intestinal amyloidosis include intestinal pseudo-obstruction,[186] and patients have been reported for whom exploratory laparotomy resulted in unnecessary morbidity. Some patients have severe intestinal dysmotility with vomiting and alternating diarrhea and constipation that can be managed only with long-term parenteral nutrition.[187] Abdominal distension and pain are common. Nausea is seen even with fasting. The mechanism underlying GI tract dysmotility can be a consequence of either direct mucosal infiltration or autonomic nerve damage.

The authors reviewed the cases of 19 patients seen at Mayo Clinic with small bowel biopsy-proven AL; these patients represented only

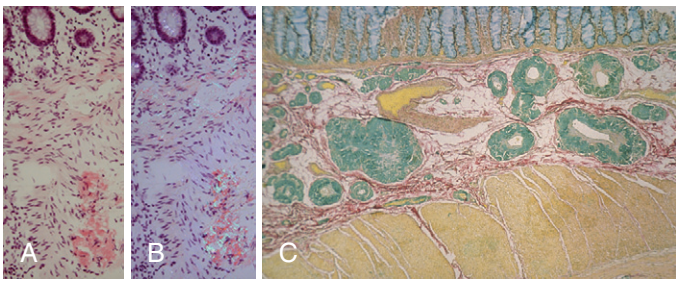

Figure 87-14 A and **B,** Gastrointestinal mucosal biopsies showing vascular amyloid deposits in the submucosa, hematoxylin and eosin and Congo Red stain. **C,** Rectal mucosal biopsy specimen demonstrates marked thickening of submucosal vessels with amyloid deposits. (Congo red; original magnification, ×100.) *(Courtesy Dr. Shu-Yuan Xiao of the University of Chicago.)*

1% of the authors' total patient population with AL.[188] The most common presenting symptoms were diarrhea, anorexia, dizziness, and abdominal pain. The median weight loss was 30 lb. Half had orthostatic hypotension. A prolonged prothrombin time caused by vitamin K malabsorption was seen in 25% of the patients. Depressed levels of factor X were also seen in 25% of patients, but only one patient had less than 30% activity. Less than one-third of the patients had increased serum alkaline phosphatase levels. Only 15% had hepatomegaly.

Barium studies of the upper GI tract showed esophageal dysmotility or gastroesophageal reflux.[189] Dilatation of the small bowel has been seen only rarely. Small bowel barium studies show thickening or nodularity, dilatation with delayed transit, and fluid accumulation. Computed tomography is not helpful, showing mild splenomegaly or lymphadenopathy. Endoscopy demonstrates esophagitis, duodenitis, and gastritis but is frequently normal.[190] The median time from the onset of intestinal symptoms to a histologic diagnosis of AL is 7 months, but in one instance, the diagnosis was delayed by 4 years. Laparotomy was performed in four of 19 patients, and even when the surgical tissue was obtained in three of the four, Congo red stains were not performed initially. The most important features predicting survival were the hemoglobin level at diagnosis and the extent of weight loss. Patients who had weight loss greater than 20 lb had a median survival time of 10 months, and the most common cause of death was nutritional failure (55%). A fourth died of cardiac amyloidosis.

The diarrhea of amyloidosis can be managed with loperamide and diphenoxylate; injections of long-acting octreotide also have been used. Ingested polyethylene glycol appears in the stool of amyloidosis patients 10 times faster than in normal subjects. These patients typically have autonomic neuropathy, which is most likely the cause of rapid transit. The severe chronic diarrhea is mediated by extremely rapid transit of chyme and digestive secretions.[191] The nausea is difficult to manage even with ondansetron. The most common preintestinal biopsy diagnosis is inflammatory bowel disease.

Primary amyloidosis can present as ischemic colitis.[192] In this circumstance, deposits obstruct the vessels of the lamina propria and muscularis mucosa, and this leads to mucosal ischemia with sloughing of the lining and bleeding[193] (Fig. 87-14, *C*). Radiographic studies demonstrate luminal narrowing, thickening of mucosal folds, and ulcerations. The most common site of ischemia is the descending and rectosigmoid colon. Duodenal perforation caused by vascular obstruction has been reported. After intestinal pseudo-obstruction develops, therapy for the underlying amyloidosis does not result in recovery of intestinal motility. Extensive replacement of the muscularis propria by amyloid deposits is particularly prominent in the small intestine.

Nervous System

Amyloid involvement of the peripheral nervous system was first described in 1938.[194] The frequency of neuropathy in AL is 15% to 20%. Most patients are minimally symptomatic, and the clinical picture is dominated by cardiac or renal involvement. If patients present with a predominant neuropathic syndrome, the possibility of a familial amyloidosis syndrome must be kept in the differential diagnosis.[195] A monoclonal protein in the serum or urine would not be expected in patients with nonimmunoglobulin forms of amyloidosis. A diagnosis of amyloid neuropathy can be confirmed by sural nerve biopsy (Fig. 87-15), but most patients with clinical and electromyographic evidence of neuropathy can be diagnosed by a fat aspirate, rectal biopsy, or BM specimen.

The most common symptoms of amyloid neuropathy are paresthesias, muscle weakness, numbness, pain, orthostatic hypotension, urinary retention, and impotence. Syncope is seen in 12% of patients. The peripheral neuropathy has a characteristic dysesthetic feature with distal burning. The lower extremities are involved before the upper extremities in 90% of patients, and symptoms of autonomic failure are seen in two-thirds. Cranial nerve involvement is rare but has been reported.[196] Carpal tunnel syndrome is present in half of patients with neuropathy. One-third have significant weight loss.

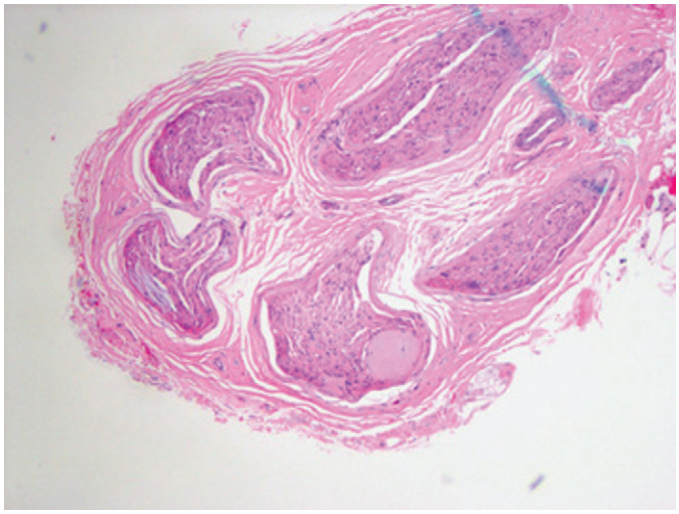

Figure 87-15 SURAL NERVE BIOPSY FOR AMYLOID INVOLVEMENT OF PERIPHERAL NERVOUS SYSTEM. The nodular deposit of pink amorphous material in the bottom center is the amyloid. *(Courtesy Dr. Peter Pytel of the University of Chicago.)*

Atypical presentations of amyloid neuropathy can include mononeuropathy multiplex, painful sensory neuropathy, and primary demyelinating polyneuropathy.[197]

Echocardiography is abnormal in 44% of patients with neuropathy. Renal involvement is uncommon, occurring in only 5%. The neuropathy of AL may be demyelinating and results in an increased concentration of cerebrospinal fluid protein in one-third. Electromyography (EMG) shows decreased amplitude of muscle action potentials, decreased or absent sensory responses, slowing of nerve conduction velocity, and fibrillation potentials.[198] Axonal degeneration is detected by EMG in 96% of patients.

On sural nerve biopsy, deposits of amyloid surround endoneurial capillaries or are found in the epineurium. Examination of teased fibers shows a decrease in myelin fiber density and axonal degeneration.[199] The median survival time of patients presenting with AL neuropathy is 25 months.[200] Standard-dose chemotherapy rarely results in clinical improvement in the neuropathic symptoms. The neuropathy is progressive over time, and three-fourths of patients ultimately have restricted mobility, with one-third becoming bedridden. Survival is predicted by the serum albumin value of these patients at presentation. Patients whose serum albumin concentration is less than 3 g/dL have a median survival time of 18 months compared with 31 months if the albumin value is greater than 3 g/dL.

Associated autonomic neuropathy is an important diagnostic clue to AL as the cause of peripheral neuropathy.[201] Urinary dysfunction is a common manifestation of autonomic failure. Voiding difficulties are caused by detrusor weakness and impaired bladder sensation. There is also evidence of detrusor denervation supersensitivity. This urinary dysfunction implicates postganglionic cholinergic and afferent somatic nerves.[202] Only diabetes mellitus generally produces a substantial autonomic component in patients with peripheral neuropathy.

The diagnosis of AL neuropathy is commonly delayed. The median duration of symptoms before diagnosis is 29 months. It is important that all patients with a peripheral neuropathy of unknown cause have immunofixation of serum and urine and an immunoglobulin free light-chain assay to search for a light chain.

The differential diagnosis of neuropathy associated with a monoclonal protein includes MGUS-associated neuropathy, POEMS syndrome (osteosclerotic myeloma), and cryoglobulinemia. Amyloidosis preferentially causes the loss of small myelinated fibers and unmyelinated fibers. EMG detects changes in large myelinated fibers. Therefore, patients can have symptoms with paresthesias and normal EMG results. The sural nerve biopsy is not 100% sensitive for the diagnosis. Of nine patients who had a sural nerve biopsy, the specimen did not

show amyloid in six.[203] Amyloid can deposit proximally in the nerve root and lead to distal demyelination, and amyloid deposits will not be seen in a sural nerve biopsy specimen.

Respiratory Tract

Most patients with histologic deposits of amyloid in the respiratory tract are asymptomatic.[204] Most patients with pulmonary involvement also have cardiac involvement that dominates the clinical picture. If alveolar or interstitial amyloid is present, gas exchange is usually preserved until quite late in the disease.[205] Of 55 patients seen at the Mayo Clinic with lung biopsy proof of amyloidosis, 20 had localized forms of pulmonary amyloidosis, predominantly nodular pulmonary amyloidosis.[206] These patients had a benign prognosis. Patients with tracheobronchial amyloidosis have been treated with neodymium: yttrium–aluminum–garnet laser therapy and external-beam radiotherapy. Thirty-five of the 55 patients had systemic pulmonary AL. These patients presented with radiographic findings of an interstitial or reticulonodular pattern with or without effusion. The median survival time after diagnosis was 16 months. Bronchoscopic lung biopsy was safe and effective and was not associated with bleeding.

Chest radiography in pulmonary AL is nonspecific, showing an interstitial process that can be interpreted as lower lobe fibrosis.[207] Involvement of minor salivary glands is common and results in xerostomia.[208] These patients can be misdiagnosed as having Sjögren syndrome. Patients with amyloidosis associated with an IgM monoclonal protein have a higher prevalence of pulmonary involvement than patients with non-IgM amyloidosis. A monoclonal gammopathy is not associated with tracheal, bronchial, or nodular pulmonary amyloidosis and is seen exclusively in diffuse interstitial amyloidosis. Long-term observation for nodular pulmonary amyloidosis is justifiable. These patients can remain stable for long periods of time without requiring resection of the lung.[209] Patients with dyspnea from interstitial amyloidosis benefit from low doses of prednisone even though this does not produce radiographic change.[210]

At autopsy, pulmonary involvement was reported in 11 of 12 deceased patients.[211] Amyloid deposition was in blood vessel walls and alveolar septa. Of the 12, dyspnea was present in four, and pulmonary amyloidosis was directly responsible for death in only one. Hemoptysis has been reported.[211] Ventilatory failure has been reported caused by muscular infiltration of the diaphragm.[212]

Amyloid infiltration of skeletal muscles and the diaphragm has been reported.[213] Pleural infiltration can produce effusions.[214] Pulmonary hypertension with right-sided cardiac failure can be seen as a rare complication.[215] These patients have occlusive amyloid deposits in the pulmonary arteriolar circulation. None of these patients had echocardiographic evidence of amyloid deposition. In the presence of pulmonary hypertension, the median survival time was 2.8 years. Treatment included calcium channel blockers; however, patients tolerated these medicines poorly owing to concomitant orthostatic hypotension.

Coagulation System

Bleeding is a serious complication of amyloidosis. Factors contributing to the abnormal bleeding include coagulation factor deficiencies, hyperfibrinolysis, platelet dysfunction, and increased fragility of blood vessels.[216] Deficiency of factor X is well recognized.[217] The most common manifestation of bleeding is purpura caused by fragile blood vessels infiltrated with amyloid.[218] Factor X deficiency is seen in fewer than 5% of patients. In a recent review, 8.7% of patients had factor X levels less than 50% of normal; serious bleeding is seen only in those with factor X levels less than 25% of normal.[219] Factor X deficiency is associated with extensive hepatic and splenic amyloidosis. Improvement in factor X levels has been reported with splenectomy,[220] use of oral melphalan and prednisone, and SCT.[221] The use of recombinant human factor VIIa in the management of amyloid-associated factor X deficiency was reported in a 63-year-old woman with levels from 4% to 10% of normal.[222] Recombinant human factor VIIa was administered preoperatively and every 3 hours postoperatively for 48 hours to permit safe splenectomy. This was an effective means of controlling bleeding to allow for definitive surgical intervention.[222] Recombinant factor VIIa has now been widely used to treat intractable life-threatening hematuria and severe bleeding and to support a hemicolectomy.[222-224]

The most common hemostatic abnormality in vitro is prolongation of the thrombin time.[225] This may be related to the low serum albumin values seen in patients with amyloidosis. Others have suggested the presence of an inhibitor to fibrin polymerization. Abnormal platelet aggregation has been reported, as have decreased levels of α_2-plasmin inhibitor and increased levels of plasminogen. Life-threatening bleeding is rare in AL, except for those few patients with severe factor X deficiency or ischemic colitis caused by vascular obstruction. Bleeding in amyloidosis has also been reported as a result of a deficiency of factor V.[226] This deficiency was not caused by acquisition of a factor V inhibitor. The bleeding in this case was fatal and unresponsive to fresh-frozen plasma. At autopsy, massive hepatic deposits of amyloid were seen.[226]

Thirty-six patients underwent extensive coagulation profiling[225]; hemorrhagic manifestations were mild to moderate in nine and severe in only one. The most frequent in vitro abnormalities were prolongation of the thrombin time and reptilase time. Severe depression of factor X was seen in only one. The prothrombin times were prolonged in eight, and the activated partial thromboplastin time was prolonged in 25. None had a lupus anticoagulant.

The authors reviewed the medical records of 2132 patients with AL to identify patients with thromboembolism.[227] They identified 21 men and 19 women with a median age of 65 years. In 11 of 40, thromboembolism preceded the diagnosis of AL. In nine of the 11, the event occurred 1 month or longer before the diagnosis of AL. In 20 of 40 patients, thromboembolism occurred 1 month or more after diagnosis. Twenty-nine had a venous thrombosis, and 11 had arterial clots. Thirty-seven of the 40 patients had an additional risk factor for thrombosis: nephrotic syndrome in 20, immobilization in 13, tobacco in six, heart failure in eight, estrogens in one, obesity in four, aortic aneurysm in one, and prosthetic material in four. Two of the patients had an associated disseminated intravascular coagulation, and five had detectable activated protein C resistance. Eight of the 40 patients died within 1 month after the thrombotic event. Eighteen of the 40 died within 1 year. There were no associations with the type of heavy or light chain.[227]

PROGNOSIS

When a patient has a syndrome compatible with amyloidosis and is found subsequently to have a monoclonal protein or clonal plasma cell population and the diagnosis is confirmed histologically, the next step is to assess prognosis. In a group of 153 patients with AL, the median survival time was 20 months, with a 5-year survival rate of 20%.[228] Patients with congestive heart failure had a median survival time of 8 months and a 5-year survival rate of 2.4%. The best outcome occurred in patients with amyloid neuropathy as the sole manifestation of the disease; they had a median survival time of 40 months and a 5-year survival rate of 32%. Patients may be classified clinically into five groups: heart failure or cardiomyopathy, nephrotic syndrome, peripheral neuropathy, liver, and other. Women have slightly better survival time than men.

In a review of 229 patients with AL, heart failure and orthostatic hypotension were associated consistently with a median survival time of less than 1 year.[25] With heart failure and nephrotic syndrome patients excluded, patients with peripheral neuropathy had a median survival time of 56 months. Jaw claudication can be seen in as many as 9%. These patients have a survival time of 42 months.[229] Patients with jaw claudication have predominantly vascular deposits and sparing of the viscera. They frequently have associated amyloid arthropathy and tongue enlargement.

The presence of hyposplenism on peripheral blood film was associated with a median survival time of 4.4 months, reflecting advanced

splenic and hepatic involvement.[230] The median survival time of 80 patients diagnosed by a liver biopsy was 9 months, and the 5-year survival rate was 13%.[169] The cause of death in most patients with amyloidosis was cardiac related—either heart failure or fatal arrhythmia. Echocardiography is important in the assessment of the patient's prognosis.[231] Although only 17% to 20% of patients have heart failure at presentation, nearly 40% have evidence of cardiomyopathy on echocardiography.[232] Early cardiac amyloidosis is characterized by abnormalities of relaxation. Advanced cardiac amyloidosis shows restrictive filling and a shortened deceleration time.[233] With Doppler echocardiography, patients can be divided into two groups on the basis of deceleration time greater or less than 150 msec. The 1-year survival of patients with a deceleration time of 150 msec or less was 49% compared with 92% for a deceleration time greater than 150 msec. Doppler studies of right ventricular function correlate well with the degree of amyloid infiltration.[234]

Findings on renal biopsy have been reported to have prognostic value.[235] A lower percentage of glomerular capillary wall thickening, a higher incidence of amyloid deposits in vessels but not glomerular capillaries, and deposits of IgG and C3 in mesangial and glomerular capillary walls are all associated with a better prognosis. Urinary light-chain excretion and serum creatinine values are also important prognostic indicators. Increased serum creatinine values are associated with a median survival time of 15 months.

Exertional syncope is an ominous finding and is associated with a high incidence of sudden death. This is usually an indication for consideration of an implantable defibrillator. Most patients with exertional syncope die within 3 months.[236]

The plasma cell labeling index measures the proliferative potential of the BM plasma cells in AL. More than 95% of patients with AL have a demonstrable clonal excess of plasma cells in the BM. The median survival time of patients whose plasma cell labeling index was 0 (no proliferative plasma cells) was 30 months. Patients with a plasma cell labeling index greater than 0 had a median survival time of 15 months.[237] Analysis of peripheral blood mononuclear cells in 147 patients with AL showed 16% of the patients to have detectable circulating plasma cells.[238] The median survival time of patients with circulating plasma cells was 10 months compared with 29 months for patients without circulating plasma cells. In a multivariate analysis, the presence of circulating plasma cells and the serum β_2-microglobulin level were independent prognostic indicators of survival.[239]

The median survival time of patients with an increased serum β_2-microglobulin value at presentation was 11 months compared with 33 months in patients with normal β_2-microglobulin values.[240] β_2-Microglobulin value is an independent predictor of survival even in the presence of heart failure and renal failure. When the serum β_2-microglobulin value is combined with the presence or absence of circulating plasma cells, patients can be classified into three separate groups with median survival times of 4 months (circulating cells and increased β_2-microglobulin), 42 months (no circulating cells and normal β_2-microglobulin), and 21 months (one of the two variables abnormal).[239]

The time between diagnosis and referral for evaluation remains an important prognostic variable. When all patients seen at the Mayo Clinic are assessed, the median survival time is 2 years. However, when only patients seen within 1 month of diagnosis are considered, the median survival time decreases to 13 months. This suggests significant referral bias, favoring patients physically able to come to a large amyloidosis treatment center. This information is important when interpreting the results of clinical trials from single centers.[126]

In a multivariate analysis of prognostic factors, the median survival time of the entire group was 12 months, ranging from 4 months for those with overt heart failure to 15 months for those with peripheral neuropathy.[241] Heart failure, urinary monoclonal light chain, hepatomegaly, and MM were all adverse factors influencing survival within 1 year after diagnosis. After the first year, increased serum creatinine concentration, MM, orthostatic hypotension, and a monoclonal serum protein predicted poor survival.[241] Stratification for the impact of variables with an adverse effect on survival is important when comparing studies of therapy among various centers.

Recently, measurement of cardiac biomarkers has been shown to be critically important in assessing the prognosis of patients with amyloidosis. Brain natriuretic peptide (BNP) is a marker of ventricular dysfunction and has been used to assess prognosis in heart failure. When N-terminal pro-BNP (NT-pro-BNP) was quantified at diagnosis in 152 patients with AL and compared with echocardiography results, two groups were distinguished on the basis of NT-pro-BNP levels.[242] Survival was vastly different in patients with elevated and normal NT-pro-BNP levels. This model for assessing prognosis was superior to echocardiography. Serum cardiac troponin value measurements combined with the NT-pro-BNP values were used in the development of a staging system for patients with amyloidosis.[243] Patients who had abnormal values for both parameters (stage III) had a median survival time of 3.5 months; those with normal values for both parameters (stage I) had a survival time of 26.4 months; and those with 1 of 2 abnormal values (stage II), 10.5 months.[243,244a] The staging system using troponins and NT-pro-BNP was subsequently verified in a cohort of patients undergoing SCT.[244] The three stages had median survival times of 66.1, 66.1, and 26.1 months, respectively.[245] Forty-nine percent of transplant patients were in stage I, 38% in stage II, and 13% in stage III. Levels of circulating cardiac biomarkers are the most powerful tool for staging patients with AL undergoing SCT.[245]

Not only has the immunoglobulin free light chain been found to be important in classifying the type of amyloidosis and providing a method for assessing response, it has also been found to be of prognostic value.[244a] Patients with higher baseline free light-chain levels had a significantly higher risk of death. Baseline free light chain correlated with serum cardiac troponin levels, and higher free light-chain levels were associated with more organs with amyloid involvement. The absolute level of free light chain achieved after therapy predicted survival. Normalization of free light-chain level after transplantation predicted both organ response and complete hematologic response. Free light-chain measurements before and after treatment are important predictors of patient outcome.[244a] The overall survival (OS) was shorter among those with a higher dFLC (involved FLC–uninvolved FLC; κ >29.4 mg/dL or λ >18.2 mg/dL using median for cutoff); 10.9 vs. 37.1 months; P <.001. In multivariate analysis, dFLC was independent of other prognostic factors. The type of light chain impacts the spectrum of organ involvement, and the FLC burden correlates with survival in AL.[244b]

In summary, all patients being assessed for amyloidosis require echocardiography, including measures of diastolic performance, ejection fraction, and mitral deceleration time. The serum β_2-microglobulin concentration, the presence of overt congestive heart failure, and circulating plasma cells remain important measures affecting outcome. BNP and troponin levels are an essential part of the diagnostic evaluation of patients with AL.

Patients with uric acid levels greater than 8 mg/dL had a median OS of 9 months from diagnosis compared with 20.3 months for the remaining patients (P <.001). The prognostic value of uric acid was independent of the known cardiac prognostic markers cardiac troponin T (cTnT) and N-terminal propeptide of BNP (NT-ProBNP). Addition of uric acid to these factors allows classification of patients into four groups with significantly different outcomes. Patients with none, one, two, or three of these risk factors (uric acid >8 mg/dL; cTnT >0.035 ng/mL; and NT-pro-BNP >332 pg/mL) had median OS times of 36.6, 29.2, 11.1, and 3.6 months, respectively (P <.001).[244c]

THERAPY

Supportive Therapy for Primary Amyloidosis

Cardiac Amyloidosis

The primary modality of therapy for cardiac AL remains diuretic agents.[246] Diuretics decrease extravascular volume, which reduces the peripheral edema that limits these patients. Diuretic therapy helps

decrease preload; filling pressures tend to be extremely high in patients with amyloidosis because of the restriction to cardiac inflow. Diuretic therapy is limited by hypotension, which, if associated with hypoalbuminemia from renal amyloidosis, can be difficult to manage.[247] Furosemide doses of 120 mg three times per day may be necessary for edema control. Metolazone can be beneficial in mobilizing fluid. Spironolactone has been shown to decrease mortality in patients with chronic heart failure, although it has not been specifically tested in amyloid cardiomyopathy. Digoxin has little beneficial effect on the diastolic heart failure seen in amyloidosis[248] but can be useful in controlling heart rate in patients with atrial fibrillation, which is generally difficult to convert to sinus rhythm. Nifedipine and diltiazem can precipitate congestive heart failure in patients with AL.[249,250] The use of angiotensin-converting enzyme inhibitors can reduce the afterload in patients with cardiac amyloidosis and has been shown to decrease mortality in patients with ischemic cardiomyopathy. In addition, lisinopril has been reported to reduce proteinuria in renal amyloidosis.[251a] Forty-five consecutive patients with EMB-documented CA were studied from January 1998 to December 2003. On univariate Kaplan-Meier analysis, New York Heart Association class greater than II, deceleration time less than 150 msec, and β-blocker use were associated with increased mortality (log-rank statistic P <.001, <.05, and .01, respectively). β-Blocker use cannot be routinely recommended for cardiac AL patients.[251b]

Orthostatic hypotension in amyloidosis can be a major problem.[252] The use of a fitted thigh-high elastic leotard can actually decrease dependence on medications. If medications are necessary, fludrocortisone acetate 0.1 mg two to three times daily can be effective, but it produces some fluid retention and can aggravate supine hypertension.[253] Midodrine can be used in doses ranging from 2.5 to 10 mg two times daily.[254] Dosing should take place during the day to avoid nocturnal supine hypertension. This agent is rapidly absorbed from the intestinal tract, and peak serum values occur in 30 minutes. The maximum recommended dose is 30 mg/day, and the medication comes in 2.5- and 5-mg tablets. If renal insufficiency is present, the dose should be decreased because active metabolites are excreted renally. Adverse effects of midodrine include tachycardia, hypertension, and restlessness. In a patient who did not respond to midodrine and fludrocortisone, subcutaneous erythropoietin resulted in resolution of symptoms related to orthostatic hypotension unassociated with improvement of anemia.[255]

Cardiac transplantation has been used for patients with advanced cardiac AL. A survey of seven patients with a mean age of 46 years reported recurrent amyloidosis in two patients at 3.5 and 4 months, one of whom died 13 months after transplantation.[256] Five patients were alive at 32 months. A follow-up study of 10 patients showed recurrent amyloidosis in the graft in four of nine survivors.[257] One patient with AL survived 9 years after cardiac transplantation.[258] Ten patients (mean age, 54 years) received heart transplants; two died postoperatively, and the mean follow-up time in the remaining eight patients was 50 months. Recurrent amyloid deposits in the cardiac allografts were demonstrable in five patients at 5 to 30 months (median, 12 months) after transplantation. Seven patients died at a median of 32 months; four of the seven died of extracardiac amyloidosis. The 1-year actuarial survival rate was 60%, and the 5-year actuarial survival rate was 30%.[258]

A 47-year-old woman with AL cardiac amyloidosis received a heart transplant followed 6 months later by SCT in an attempt to prevent recurrent disease.[259] The patient died 2 years after SCT, and the myocardium showed mild deposits of amyloid.[259] In 13 cardiac transplant patients with AL at the Mayo Clinic, the actuarial 5-year survival rate was 50%.[260] The authors have performed SCT in 11 patients who were recipients of cardiac transplants; five died and six were alive at 18, 19, 22, 23, 59, and 82 months after SCT.

One study queried the United Network for Organ Sharing database and found 69 patients with amyloidosis who had cardiac transplants.[261] Five operative deaths occurred, and 29 late deaths occurred at a mean follow-up time of 40 months. Nine patients died of amyloid-related complications, and graft vasculopathy developed in one patient. The 1-year survival rate was 84% for men and 64% for women.[261] In a report from the United Kingdom, 24 patients had amyloid heart disease, 17 of whom had AL.[262] The survival rate of 10 patients was 50% at 1 year and 20% at 5 years after heart transplant. Amyloid recurrence in the grafts occurred at a median of 11 months. Extracardiac amyloid contributed to mortality in 70%. Seven patients with AL who also had chemotherapy had 1- and 5-year survival rates of 86% and 64%, respectively. The survival rate was less than after transplant for other indications. Progression of the AL contributed to the increased mortality.[262]

In a single-center report of five patients with cardiac AL, three were dead and two were alive at 60 and 41 months after transplant.[263] Two patients died of sudden death after 23 months and one of multiorgan failure because of progression of AL.[263] Because recurrent amyloidosis is such a common cause of morbidity, the use of SCT to prevent disease recurrence after heart transplantation (HT) has been reported. Five patients had SCTs after heart transplant, and three of the five were well without evidence of recurrent amyloid.[264] Two patients died at 33 and 90 months after heart transplant after relapse of the amyloidosis.[264a] Between 1994 and 2005, 11 patients underwent sequential orthotopic HT followed by autologous peripheral blood SCT for treatment of AL amyloidosis at the Mayo Clinic. Two patients died of complications from the SCT (18% transplant-related mortality). Nine patients survived both the HT and the SCT. Three patients subsequently died from progressive amyloidosis at 66, 56.7, and 55 months after SCT. The 1- and 5-year survival for HT was 82% and 65%. The median survival was 76 months from HT and 57 months from SCT. Two patients died of complications from the SCT (18% transplant-related mortality). Nine patients survived both the HT and the SCT. Three patients subsequently died from progressive amyloidosis at 66, 56.7, and 55 months after SCT. The 1- and 5-year survival rates for HT were 82% and 65%, respectively. The median survival rate was 76 months from HT and 57 months from SCT. HT followed by SCT is feasible and offers the possibility of remission for carefully selected patients with cardiac amyloidosis.[264b]

Renal Amyloidosis

Diuretics can manage the edema of nephrotic syndrome. For patients in whom renal failure eventually develops, hemodialysis support is required. The results of dialysis in AL patients are inferior to those in patients with primary kidney disease.[265] In 61 patients with amyloidosis who had dialysis, 18 died within 1 month after starting therapy, and 43 underwent dialysis for more than 1 month. Younger patients had better 5-year survival times. The most important complications after initiation of dialysis were the subsequent development of cardiac and intestinal amyloidosis. Survival was not different between amyloidosis patients who received hemodialysis and those who received peritoneal dialysis.[265] Two-thirds of the deaths in the patient population were caused by extrarenal amyloidosis progression, primarily cardiac.[133]

The use of lisinopril has been reported to decrease proteinuria in patients with nephrotic syndrome and can result in significant hyperkalemia. Enalapril has been reported to be effective in reducing proteinuria in steroid-resistant nephrotic syndrome.[266] The mechanism of action is thought to be hemodynamic and is potentially effective in amyloidosis as well.

Renal transplantation has been used in patients with AL. Recurrent amyloidosis in the graft remains a major problem, however. The authors have performed renal transplantation in eight patients, six of whom had stem cell harvest; five of them underwent SCT.[142] Stable renal function was present in four. Sequential kidney and SCT is feasible.[142] Others have argued that SCT should precede kidney transplantation in an effort to produce a complete response before placement of the new organ.[143]

Survival is linked to the development of amyloidosis in the graft; it has been estimated that 1-year survivors have a 20% chance of amyloidosis developing in the transplanted kidney. Fifteen patients with renal amyloidosis underwent transplantation and had 42 to 216 months of follow-up (median, 73 months).[267a] The grafts remained

normal in all patients whose underlying amyloidogenic disorder had remitted. If the underlying precursor protein production had not remitted, abnormal uptake of radiolabeled serum amyloid P was found, reflecting the development of amyloid in the transplanted kidney. Patients with evidence of renal amyloid by serum amyloid P scan also had evidence of graft dysfunction.[267a]

Three patients were reported who received kidney transplants after monoclonal light-chain synthesis was suppressed by chemotherapy.[267a] The response to chemotherapy was documented by eradication or reduction of immunoglobulin light-chain production. Three patients were alive at 4, 11, and 16 years after transplantation. Renal function in the AL patients remained normal. Renal transplantation is therefore appropriate for patients whose light-chain production can be suppressed.[266] The feasibility of sequential living donor kidney transplantation and autologous SCT for carefully selected patients with end-stage renal disease caused by AL has been established.[142] Disease recurrence remains a problem, particularly for inherited forms of amyloidosis.[267b]

Hepatic Amyloidosis

As is the case for all other types of AL, the mainstay of therapy for hepatic amyloidosis is suppression of the underlying plasma cell clone with chemotherapy. However, liver transplantation has been reported for the management of AL. A 61-year-old man was hospitalized for spontaneous splenic rupture.[268] Shortly after splenectomy, liver failure with jaundice, ascites, and hyponatremia developed. A subsequent hepatorenal syndrome with hepatic encephalopathy developed over 3 weeks. Hepatic transplantation was performed, and the patient was dismissed from the hospital with normal hepatic and kidney function. At 1-year postoperative follow-up, liver function was normal, although a liver biopsy showed amyloid deposits in the hepatic allograft.[268] Another patient with progressive hepatic failure from AL received a liver allograft.[269] The patient had development of recurrent amyloidosis that led to SCT in an effort to suppress amyloid precursor protein production. After a second (tandem) transplantation procedure, the patient had no clinical evidence of recurrent amyloidosis at 28 months. Liver transplantation can be considered for patients with amyloidosis, but suppression of light-chain production is essential to prevent recurrent disease.[269] Liver transplantation is primarily used to manage familial forms of amyloidosis and rarely used as a tool for management of light-chain amyloidosis.

Gastrointestinal Tract Amyloidosis

The most frequent symptoms related to amyloidosis of the GI tract are diarrhea and constipation. In most patients, these are caused by autonomic failure, but in some patients, massive deposits develop in the mucosa and submucosa and result in a malabsorption syndrome. Loperamide, diphenoxylate, tincture of opium, and paregoric are used regularly and produce variable results. Octreotide in a long-acting formulation can decrease diarrhea when given in doses ranging from 10 to 30 mg every 4 weeks for 2 months and then every 4 weeks, according to the response of the diarrhea. Rarely, ostomies are required for diarrhea control. Occasionally, widespread vascular obstruction of blood supply to the bowel develops, leading to massive bleeding and infarction for which surgical intervention is the only option. For nausea, abdominal distension, and pain, cisapride has been reported to provide symptomatic relief.[270]

Noncytotoxic Chemotherapy for Primary Amyloidosis

The primary approach to therapy has been to decrease production of the amyloidogenic light chain with therapy directed against the plasma cell population. DMSO has been used because of in vitro data suggesting an ability to solubilize amyloid deposits.[271] The benefit of DMSO is unproven, and it is infrequently used today to treat amyloidosis.[272] Colchicine has been shown to be effective in the treatment of AA associated with familial Mediterranean fever, a disorder characterized by recurrent peritonitis, pleuritis, synovitis, and rash. Before the introduction of colchicine, the 5-year survival rate of patients with familial Mediterranean fever was 20%. Nephrotic-range proteinuria and dialysis-dependent renal failure developed in these patients. Two double-blind, placebo-controlled trials showed that colchicine was effective in preventing attacks of serositis and reduced the frequency of amyloidosis.[273]

Given the success of colchicine for familial Mediterranean fever amyloidosis,[274] it was used in patients with AL. Fifty-three patients with AL received colchicine and were compared with retrospective control participants.[275a] The median survival time of colchicine-treated patients was 7 months compared with 1 year in melphalan-treated patients.[275a] Today, colchicine is rarely used for AL. Colchicine is not effective for any of the hereditary periodic fever syndromes including hyperimmunoglobulinemia-D with periodic fever, tumor necrosis factor receptor–associated periodic syndrome, and cryopyrin-associated periodic syndrome.[102]

Cytotoxic Chemotherapy for Primary Amyloidosis

The same chemotherapy drugs used to treat amyloidosis have been used for the management of MM. These include oral melphalan and prednisone; oral dexamethasone; and combination chemotherapy, including thalidomide-, lenalidomide-, and bortezomib-based therapies. These therapies can decrease the plasma cell burden to some degree. Many patients die of the disease before adequate time has elapsed to determine if they will achieve a response. The best predictors for early attrition during cycle 1 of chemotherapy were TnT 0.07 μg/L or greater and NT-proBNP 11,939 ng/L or greater. NT-proBNP response underperformed TnT response as a predictor for OS, but both predicted for early protocol attrition and inability to tolerate therapy, rendering a proportion inevaluable for response.[275b] Two prospective, randomized studies have demonstrated a survival benefit for oral melphalan and prednisone compared with colchicine.[276,277] Unfortunately, the median survival time is prolonged to only 17 or 18 months.

Responders to melphalan and prednisone have prolonged survival times compared with nonresponders.[228] Patients who have nephrotic syndrome have a better outcome in terms of response rate than those who have peripheral neuropathy or cardiac involvement. It is unclear whether clinical organ improvement is associated with histologic regression because follow-up biopsies are done infrequently. However, the use of serum amyloid P component scanning has indicated decreased uptake of the isotope at sites of previously known disease, which suggests resolution of the amyloid deposits. Melphalan is leukemogenic, and the risk of myelodysplasia developing is substantial.[278a] The authors identified 10 patients with myelodysplasia or acute myeloid leukemia that directly caused death for eight and transfusion dependency for two. Two of the 10 patients did not have development of myelodysplasia until 144 months after first exposure to alkylating agents. The actuarial risk of myelodysplasia development at 10 years was 18%.[278b]

We have reported that even in the presence of significant cardiac amyloidosis, survival of more than 5 years was seen in eight of 153 patients.[279] All long-term survivors received chemotherapy. All but one had a demonstrable response to chemotherapy. Continuous oral melphalan has been administered as a single agent for patients with cardiac amyloidosis who could not tolerate prednisone or SCT. Seven of 13 evaluable patients achieved a partial hematologic response, three achieved a complete hematologic response, and six survived for longer than 1 year. Continuous low-dose oral melphalan can induce hematologic responses.[280]

Responses to melphalan and prednisone are uncommon if the serum creatinine value exceeds 3 mg/dL, if hyperbilirubinemia is present, or if the alkaline phosphatase value increases to more than four times the institutional normal.[228] In patients who have isolated nephrotic syndrome, a normal serum creatinine value, and a normal

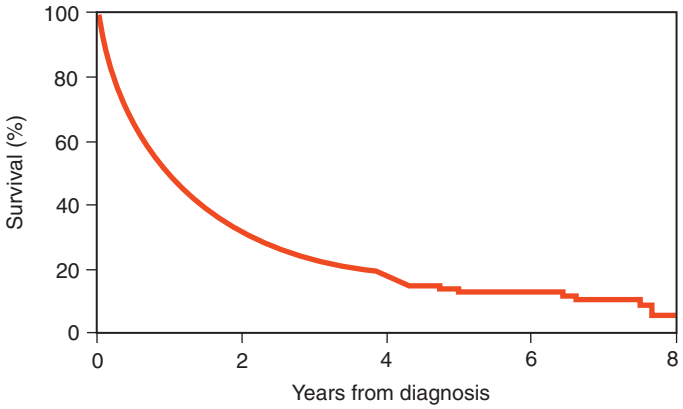

Figure 87-16 OVERALL SURVIVAL OF PATIENTS SEEN AT THE MAYO CLINIC WITH AMYLOIDOSIS.

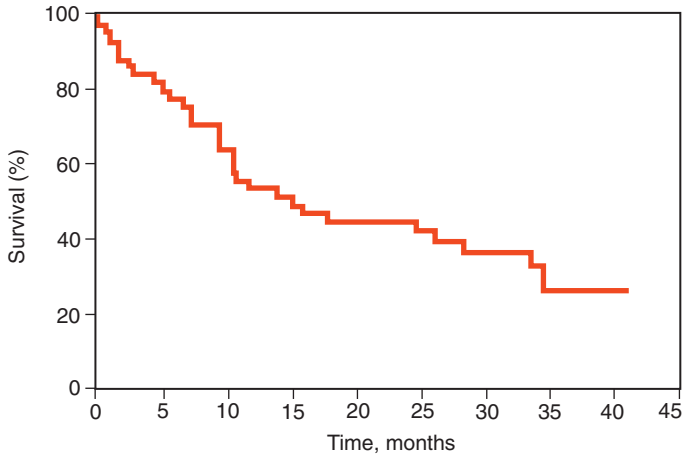

Figure 87-17 SURVIVAL OF 55 PATIENTS WITH AMYLOIDOSIS TREATED WITH HIGH-DOSE DEXAMETHASONE.

echocardiogram, the response rate to melphalan can exceed one-third of patients. It is rare to see symptomatic improvement in peripheral neuropathy after melphalan and prednisone therapy. The median time to response with melphalan is 1 year.[228]

In a 21-year period at the Mayo Clinic, 841 patients with AL were evaluated.[281] The actuarial survival for the 810 patients diagnosed premortem was 51% at 1 year, 16% at 5 years, and 4.7% at 10 years (Fig. 87-16). The authors reported on 30 patients with survival for 10 years after diagnosis, all of whom received melphalan-based therapy.[281] Fourteen had complete eradication of the light chain from serum and urine. Of 10 patients with nephrotic syndrome, four had a greater than 50% reduction in proteinuria. Heart failure, older age, a creatinine value greater than 2 mg/dL, and BM plasma cells greater than 20% were poor prognostic factors for long-term survival.[279,280]

Four patients in whom alkylating agents had failed were treated subsequently with vincristine, doxorubicin (Adriamycin), and dexamethasone (VAD) as a 96-hour infusion.[282] Two of the patients had a 50% decrease in the serum monoclonal protein. The VAD regimen could be considered for patients with AL and has been reported as an induction treatment to decrease the plasma cell burden before SCT.[282] The use of VAD resulted in improvement in patients' conditions, allowing them to receive high-dose chemotherapy and SCT with reduced risk.[282] A series of patients from a single institution had successful use of VAD induction followed by melphalan-based SCT.[283,284]

In a three-arm study that accrued 219 patients over 10 years, patients were randomly assigned to receive colchicine; melphalan and prednisone; or melphalan, prednisone, and colchicine.[276] Patients were stratified by age, sex, and major clinical manifestation of amyloidosis. Half had nephrotic-range proteinuria, and 20% had heart failure. The colchicine group survived a median of 8.5 months, and the melphalan-containing regimens resulted in survival times of 17 months. Similar results were reported in patients treated with melphalan at Boston University.[277] The authors reported on the development of myelodysplasia in 10 of 153 patients who were treated with melphalan for AL.[278] Eight of the 10 died as a result of the myelodysplasia, including acute leukemia and progressive pancytopenia caused by myelodysplasia. This group represents 7% of all patients treated with melphalan; the actuarial risk for survivors at 3.5 years was 21%. The median survival time after the diagnosis of myelodysplasia or acute leukemia was 8 months. As the survival of patients with plasma cell disorders improves, myelodysplasia may be a more common cause of morbidity and mortality for this group.[278b]

In one patient, the diagnosis of amyloidosis was established, and the patient received 28 months of oral melphalan, prednisone, and colchicine.[285] Five years later, he had dialysis-dependent renal failure with no other evidence of amyloidosis and received a renal transplant. He survived for 7 years; pancytopenia developed with BM that showed dysplastic red blood cells but no acute leukemia. Cytogenetics were complex but included a 5q abnormality. Myelodysplasia developed 12 years after his diagnosis of amyloidosis.

High-dose dexamethasone as a single agent given at 40 mg on days 1 to 4, 9 to 12, and 17 to 20 every 5 weeks has been reported.[286] Responding patients received maintenance dexamethasone at 40 mg/day 4 days per month for 1 year. Improvement in amyloid organ involvement was seen in eight of nine patients, and six of seven had a greater than 50% decrease in urinary protein loss with a median time to response of 4 months. Patients with heart failure did not benefit. The median survival time of the cohort was 31 months. In a report on 93 patients treated with this regimen, 2-year OS was 60%, and event-free survival was 52%.[287] Heart failure and β_2-microglobulin levels were the predictors of adverse outcome.[287] The authors treated 19 patients with high-dose dexamethasone therapy,[288] and three showed objective organ response. The median survival time of the entire group was 11.2 months, but three patients were alive at 110, 116, and 119 months. Dexamethasone should be considered as an option for patients who are not suitable candidates for transplantation. Dexamethasone has also been used for patients in whom melphalan therapy had previously failed.[289] The objective response rate was 12% (Fig. 87-17). One patient was alive at 104 months.

Because high-dose dexamethasone therapy can be toxic in patients with AL, a reduced-dose schedule has been reported: 40 mg on days 1 through 4 every 21 days for up to 8 cycles.[290] Overall, eight of 23 patients had a median time to response of 4 months (range, 2-6 months). This regimen has been used as a first-line therapy. This same group reported on the combination of low-dose melphalan and modified high-dose dexamethasone therapy.[290]

Melphalan has been combined with high-dose dexamethasone in patients with AL who were ineligible for SCT, primarily because of cardiomyopathy.[291a] Of 46 patients, a complete response was seen in 15 (33%) and a hematologic response in 31 (67%). Twenty-two patients (48%) showed an improvement in organ dysfunction. There was a strong correlation between hematologic and organ response. If the hematologic response was complete, the organ response rate was 87%. If the hematologic response was greater than 50%, organ function improved in 56%; patients with no hematologic response had no organ functional improvement. The 100-day mortality rate with this regimen was 4%. Cardiac failure resolved in six of 32 patients. The median time to response was 4.5 months, and only 11% had adverse effects.[291a] Using a similar melphalan-and-dexamethasone–based regimen, physicians at Weill-Cornell School of Medicine reported a median survival time of only 10.5 months. Outcomes appear to be strongly linked to the proportion of patients with cardiac amyloidosis.[291b] With melphalan administered parenterally with dexamethasone in patients with immunoglobulin light-chain amyloidosis, the median survival time of 61 patients was 17.5 months. The 3-month mortality rate was 28%.[291c] In Boston, of 48 evaluable patients who survived and returned for follow-up assessment, six patients (13%) achieved a complete hematologic response and 12

patients (25%) a partial hematologic response. Responses were noninferior for patients receiving weekly "low-dose" dexamethasone compared with those receiving 4-day pulses. The median survival time for the 70 patients has not yet been reached with a median follow-up of 17 months.[299d] There appear to be two factors that help account for at least some of this difference. The first is that the assessment of response using the immunoglobulin-free light-chain assay did not exist in the early studies of melphalan-based therapy but has been used regularly since 2005, resulting in improved ability to monitor hematologic responses. Second, the mix of patients, particularly cardiac, is very important in determining overall outcomes.

The authors studied 101 patients with AL; half received melphalan and prednisone, and half received vincristine, carmustine, melphalan, cyclophosphamide, and prednisone.[292] Seventy-six of the 101 patients died, and the median OS for the entire group was 26.4 months, with no difference between the two arms. In this group of 101, 18 patients ultimately required dialysis therapy; 15 of the 18 have since died. The most common cause of death was intractable hypotension related to cardiac involvement while on dialysis. The three surviving dialysis patients have been alive for 87, 94, and 103 months. A myelodysplastic syndrome was documented in eight patients, all of whom have died, including one who received an allogeneic BM transplant. The OS time of these eight patients ranged from 18 to 90 months, with a median of 43 months. The authors also studied 45 patients who received the agent iodo-deoxydoxorubicin and found a response rate of 15%.[293]

Thalidomide has been shown to be active in the treatment of AL. In the initial report, six patients with AL were treated with thalidomide.[294] All patients had renal amyloidosis and were treated previously. The duration of thalidomide therapy was 3 to 9 months (median, 5 months). Four also received oral corticosteroids. An improvement was reported in five patients. Proteinuria decreased by more than 50% in two, and the serum albumin concentration improved in three. Two patients died, and four were alive and remained on therapy.[294]

In another report of 12 patients receiving thalidomide, eight patients had renal, four had cardiac, three had liver, and two had soft tissue amyloidosis.[295] Ten had received prior SCT. The median maximum tolerated thalidomide dose was 50 mg. No patient had a 50% decrease in serum or urine monoclonal proteins. Five of 11 patients had a 25% to 50% improvement. Three patients had stable disease, and three had progressive disease.[295] The authors have found thalidomide difficult to administer, and initial doses should not exceed 50 mg. It is unusual for patients with amyloidosis to tolerate more than 200 mg/day long term, and the toxicity is substantially greater in this population. The authors encountered edema and cognitive difficulties in 75%; dyspnea, dizziness, and rash in 50%; and two deep venous thromboses. The median time on treatment was only 72 days.[296,297]

Thalidomide has been combined with dexamethasone therapy in 31 patients.[298] Forty-eight percent of patients achieved a hematologic response, with 19% complete responses and 26% organ responses. The median time to hematologic response was 3.6 months. Treatment-related toxicity was frequent at 65%.[298]

Lenalidomide has been reported to be useful in the treatment of amyloidosis. A report on 34 patients was recently presented[299a]; eight of the 13 evaluable patients had a measurable response, four to lenalidomide alone. Nine other patients responded when dexamethasone was added. Lenalidomide appeared to be better tolerated than thalidomide.[299a]

Eighty percent of evaluable patients in the first study of bortezomib for amyloidosis had a hematologic response.[299b] Among 18 patients, the hematologic response was 77% with 16% being complete. A phase I dose-escalation study of bortezomib given either twice weekly on days 1, 4, 8, and 11 every 21 days or days 1, 8, 15, and 22 every 35 days reported hematologic responses in 50% of patients. The weekly regimen was associated with lower neurotoxicity. There is a 1-year hematologic progression-free rate of 72.2% and 74.6% and 1-year survival rates of 93.8 and 84%, respectively, for the twice-weekly and once-weekly dose.[299c] Among 70 patients, there were 29% renal and 13% cardiac responses. Discontinuation and dose reduction because of the toxicity were higher with the twice-weekly than once-weekly dose. Both dose schedules represent active well-tolerated regimens in relapsed AL.[299d]

The combination of bortezomib and dexamethasone has been used after SCT as consolidation therapy to improve the depth of response.[299e] Seventeen of 23 patients received bortezomib after transplantation; 74% achieved a complete response, and 58% achieved an organ response. A multicenter study of 94 patients receiving bortezomib and dexamethasone showed that hematologic responses in 71%; 25% were complete.[299f] Cardiac response was seen in 29% of patients. NT-proBNP predicted survival. In a study of bortezomib–dexamethasone in 26 patients, the overall response rate was 54% with 31% complete responses. The median time to response was 7.5 weeks, but the median progression-free and OS times were 5 and 18.7 months, respectively, suggesting short durability with bortezomib combined with dexamethasone. No grade 3 or 4 neuropathy was observed.[299g]

Lenalidomide has been combined with melphalan and dexamethasone.[299h] The maximum tolerated dose of lenalidomide is 15 mg. This three-drug oral combination produced hematologic responses in 58% and complete responses in 42%. The 2-year event-free and OS rates were 54% and 81%, respectively. Lenalidomide has also been combined with cyclophosphamide and dexamethasone in 35 patients.[299i] The hematologic response rate was 60%. In those receiving at least 4 cycles, the response rate was 87%. The OS time was 16.1 months. A randomized study of cyclophosphamide–thalidomide–dexamethasone compared with melphalan–dexamethasone suggested a higher complete response rate with the three-drug regimen, albeit with greater toxicity.[299j] One cautionary note when using lenalidomide or thalidomide in patients with light-chain amyloidosis is that the NT-proBNP appears to rise after the initiation of therapy. Recognition of potential IMID-induced cardiac toxicity is important when these agents are used. High levels of NT-proBNP predict for an inability to tolerate immunomodulatory agents for amyloidosis.[299k,299l]

Pomalidomide, a derivative of thalidomide with structural similarity to thalidomide and lenalidomide, was given to 26 patients in one study. All patients were previously treated. Half received a prior autologous SCT. A prior immunomodulatory agent was given in 12 and prior bortezomib in nine. Nineteen patients evaluable for hematologic response were seen. The overall response rate was seven of 19 (35%). Pomalidomide and dexamethasone is promising for the treatment of amyloidosis. One-year overall and progression-free survival were 77% and 56%, respectively. Pomalidomide was considered effective and safe, including for patients failing prior lenalidomide or thalidomide therapy.[299m]

STEM CELL TRANSPLANTATION FOR PRIMARY AMYLOIDOSIS

The use of high-dose chemotherapy and SCT for patients with amyloidosis remains controversial because this modality of therapy is associated with a high treatment-related mortality (Table 87-4).[300-313] Transplant-related mortality rates can range from 7% to 43%. Moreover, mortality has even been reported during stem cell mobilization using granulocyte colony-stimulating factor (G-CSF); these deaths were attributed to noncardiogenic pulmonary edema,[314] cardiac ischemia, or sudden rhythm disturbances with ventricular fibrillation. The significant visceral organ dysfunction that accompanies amyloidosis places patients at a high risk for complications. The number of organs involved at the time of transplantation is predictive of outcome. Patients who have one organ involved fare better than those who have two, and those who have more than two organs involved have an even poorer outcome.[315] Causes of treatment-related mortality in AL include GI tract bleeding,[316] cardiac rhythm disturbances, and multiorgan failure.

At the Mayo Clinic, high-dose chemotherapy and autologous SCT have been performed in 434 patients with AL. The median age was 57 years. The median serum albumin level was 2.7 g/dL, which

Table 87-4 Results of High-Dose Chemotherapy and Autologous Stem Cell Transplantation for Amyloidosis

Reference	Patients *(n)*	100-Day Treatment-Related Mortality	Overall Survival (Intention to Treat)
Perfetti et al[351]	22	3 (14%)	Median, 68 months
Sanchorawala et al[352]	80	11 (14%)	Median, 57 months
Dimopoulos et al[353]	50	12 (24%)	Median, 22.2 months

reflects a high prevalence of nephrotic-range proteinuria. Ten percent of patients had serum creatinine levels greater than 1.8 mg/dL. Alkaline phosphatase levels greater than twice normal, a marker for liver amyloidosis, were observed in 58 (13%) patients. The median serum monoclonal protein concentration was 0.1 g/dL. A serum monoclonal protein component was found in 341 of the 434 patients (79%). The median 24-hour urine protein excretion was 3.7 g/day (interquartile range, 0.28-7.45 g/day). Fifty-six percent had urinary protein loss greater than 3 g/day. Only 8% had monoclonal light-chain excretion of greater than 1 g in 24 hours. One-, two-, and three-organ amyloid involvement was seen in 47%, 39%, and 14% of patients, respectively.

Stem cell mobilization in patients with amyloidosis was achieved with G-CSF alone without prior cytotoxic chemotherapy. The median number of apheresis collections required to collect an adequate stem cell product was 2 (interquartile range, 1-4 apheresis). The median number of $CD34^+$ cells collected was 7.16 × 10(6) CD34 cells (interquartile range, 4.92-9.84 × 106 CD34 cells). Hematopoietic growth factors were not administered after transplantation because of their ability to produce fluid retention in patients with cardiac and renal amyloidosis.

The 100-day mortality rate of these patients was 10.1% (44 of 434 patients), which compares favorably with reports from other institutions where morality rates as high as 40% have been reported.[307a] Mortality rates (before day 100) at the Mayo Clinic have progressively decreased over the years: outcomes of patients treated before January 2006 with those treated from January 2006 to December 31, 2009. Day 100 mortality decreased over this time period from 12% to 7%.[307b] Sixty-six percent of patients received conditioning therapy with melphalan at a dose of 200 mg/m^2, 29% received melphalan at 140 mg/m^2, and the rest received lower doses because of advanced cardiac amyloidosis. The intensity of chemotherapy delivered appears to be predictive of outcome.[317a] Patients receiving full-dose melphalan fare better, although patients selected for full-intensity therapy tend to have less advanced disease and are somewhat younger.[317a] Among 271 patients undergoing SCT, troponin T was a powerful predictor of treatment-related mortality. Patients with troponin T levels of 0.06 μg/L or higher had a day-100 all-cause mortality rate of 28%. Patients with troponin T levels less than 0.06 μg/L had a day-100 all-cause mortality rate of 7% (P <.001). Troponin T levels should be measured in all patients before transplantation. Those with troponin T levels exceeding 0.06 μg/L should be considered for less toxic therapies until the clinically optimal use of SCT is better defined by randomized clinical trials (see box on Guidelines for Exclusion of Patients From Consideration of Stem Cell Transplantation).[317b]

Bias is inherent in selecting patients for transplantation and the intensity of their conditioning. At the Mayo Clinic, only one-fifth of patients encountered with amyloidosis ultimately go on to receive SCT. Transplant recipients survive longer than patients not selected for transplant. In a case-matched control study, 63 transplant patients were compared with 63 conventionally treated patients matched for

Guidelines for Exclusion of Patients From Stem Cell Transplantation

Absolute contraindication
- Clinical congestive heart failure
- Total bilirubin >3.0 mg/dL
- Echocardiographic ejection fraction <30%

Troponin T >0.06

Relative contraindication
- Serum creatinine >2.0 mg/dL
- Interventricular septal thickness >15 mm
- Age older than >60 years
- More than two visceral organs involved

From Gertz MA, Lacy MQ, Dispenzieri A: Immunoglobulin light chain amyloidosis (primary amyloidosis, AL). In Gertz MA, Greipp PR, editors: *Handbook of multiple myeloma and related cell disorders.* New York: Springer-Verlag, 2010. By permission of Mayo Foundation for Medical Education and Research.

age, sex, cardiac function, creatinine, urinary protein loss, and liver involvement. An overall survival advantage for the patients undergoing transplant was observed.[318] In a report from the American Bone Marrow Transplant Registry of 107 patients treated with high-dose chemotherapy and autologous SCT at 48 centers,[319] the 30-day treatment mortality rate was 18%, and the response rate was 34%, with 33% having stable disease.[319] Only 11% of patients had posttransplant disease progression. The projected median survival time was 47 months. Experienced transplant groups appear to be able to achieve similar results as those of centers with a special interest in amyloidosis and transplantation.[320]

The 434 Mayo Clinic patients with amyloidosis received their transplants a median of 4.0 months after histologic diagnosis: one-fourth within 3 months and three-fourths within 6.6 months. The median actuarial survival time for the entire group was 94.9 months. Predictors of survival included weight gain of greater than 2% during stem cell mobilization and an absolute lymphocyte count at day 15 of greater than 500/μL.[321] The number of organs involved appeared to be relevant to successfully predicting outcome (Fig. 87-18). Patients with two-organ involvement have a survival rate of 70% at 60 months; those with three-organ involvement have a median survival time of 58 months. The serum creatinine, troponin-T, and BNP levels (Fig. 87-19) and septal thickness were all significant predictors of outcome.

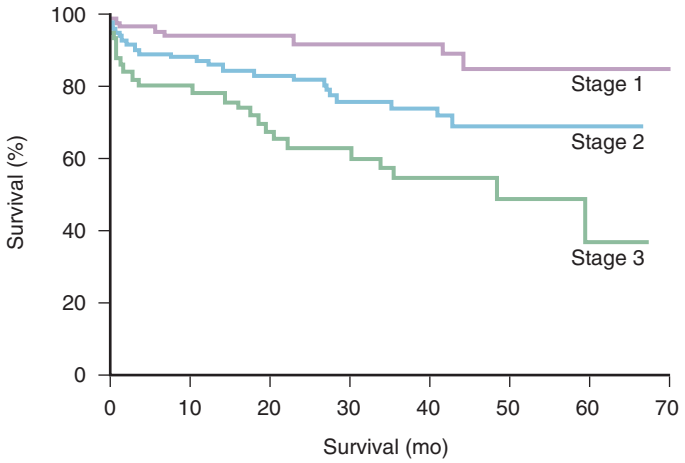

Figure 87-18 KAPLAN-MEIER CURVES ESTIMATING SURVIVAL IN 430 MAYO CLINIC PATIENTS WITH AMYLOIDOSIS ON THE BASIS OF MAYO STAGE AT PRESENTATION.

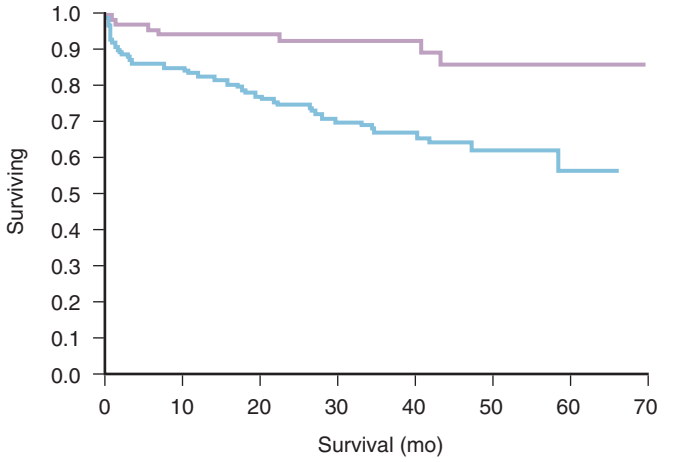

Figure 87-19 KAPLAN-MEIER CURVES ESTIMATING SURVIVAL IN 169 MAYO CLINIC PATIENTS WITH AMYLOIDOSIS ON THE BASIS OF N-TERMINAL PRO-BRAIN NATRIURETIC PEPTIDE (NT-pro-BNP) CONCENTRATION GREATER OR LESS THAN 333 pg/mL ($P = .002$).

Stem cell transplantation has not yet been established as the therapy of choice for patients with amyloidosis. In a French multicenter randomized trial (MAG and IFM Intergroup), patients with amyloidosis received either high-dose chemotherapy and autologous SCT or melphalan–dexamethasone therapy.[322a] The median survival time was 57 months in the melphalan–dexamethasone group and 49 months in the transplant group. Transplant patients received conditioning chemotherapy with either 140 or 200 mg/m^2 of melphalan. The hematologic response rates were similar for both groups (65% vs. 64%). These results suggest that OS may not be superior after SCT compared with melphalan–dexamethasone therapy.[322a] The results of this study must be interpreted with caution because of the short median follow-up (29 months) and high transplant-related mortality (24%). In a published meta-analysis of SCT in AL, transplantation does not appear to be superior to conventional chemotherapy in improving survival in patients with AL. But the quality of evidence is low, indicating a need for well-designed and adequately powered randomized, controlled trials to better address the role of transplantation in AL.[322b]

After transplant, responders to autologous SCT have a superior survival rate compared with nonresponders. OS is linked to pretransplant-free light-chain levels and the number of organs involved.[244,317a] In centers performing SCT, the treatment-related mortality rate has ranged from 6% to 18%, hematologic complete responses from 16% to 50%, and organ responses from 34% to 64%.[323] Organ responses are time dependent and may be delayed for up to 36 months after transplantation. The use of induction therapy with 2 cycles of melphalan and prednisone before SCT did not improve the rate of hematologic or organ response.[324]

Deaths have been reported during stem cell mobilization with cyclophosphamide plus G-CSF or G-CSF alone.[325] Hypoxia and hypotension may develop even in patients without cardiac involvement and may reflect a variant of pulmonary leukostasis syndrome. Excessive fluid accumulation during stem cell mobilization is an important predictor of 1-year survival.[326]

Toxic megacolon is a complication of high-dose chemotherapy.[327] Others have also reported fatal cardiac arrhythmias after infusion of DMSO-cryopreserved stem cell grafts.[328,329] The absolute numbers of CD4$^+$ T cells is significantly reduced after SCT, raising the theoretical risk that serious opportunistic infections will develop after transplantation. In a series of six patients, four had acute renal failure, one had splenic rupture, and one had severe GI bleeding.[330,331] In a multicenter study of 15 transplant patients, there was no treatment-related mortality, and 67% of patients experienced complete hematologic responses, suggesting the feasibility of performing SCT at experienced transplant centers not associated with major amyloidosis referral centers.[332]

Amyloid-related cardiomyopathy is associated with a high rate of early mortality after transplant.[333] The median survival time of patients with cardiac amyloidosis was 2 years. The overall median survival time was 5.5 years, and the relapse rate of complete responders was only 5%.[333]

Most conditioning regimens used to treat patients with AL undergoing transplant include melphalan; currently, melphalan alone is preferred to melphalan plus total-body irradiation. Complete hematologic response rates appear to be related to the dose of melphalan: 55% at 200 mg/m^2 and 35% at 100 or 140 mg/m^2.[317a] GI tract bleeding is a frequent complication.[316] It is assumed that amyloid infiltration of the submucosa of the GI tract followed by chemotherapy-induced mucosal erosion leads to exposure of amyloid-laden blood vessels with resultant bleeding.

Despite the high mortality and morbidity associated with transplantation (Table 87-5), the hematologic and organ response rates far exceed the prior experience with conventional-dose melphalan. Improvement in quality of life has also been reported in melphalan-treated patients undergoing SCT.[334] The best responses to transplant are seen in patients who have renal amyloidosis and nephrotic syndrome. The authors believe that the dose of melphalan used for conditioning must be modified according to patient risk factors. Clearly, patients with more than two major organs involved or severe

cardiomyopathy are at a high risk when receiving melphalan doses of 200 mg/m^2 (Fig. 87-20). Patients with one or two organs involved, younger patients, and those without advanced cardiac disease are favorable candidates for SCT. A risk-adapted stratification has been useful in selecting patients for therapy and assigning melphalan dose (see box on Risk-Adapted Approach to Chemotherapy Dosing in Stem Cell Transplant Recipients).[317a]

The use of both conventional and high-dose chemotherapy has been shown to normalize factor X deficiency associated with amyloidosis.[335] Dose-intensive melphalan therapy improves nephrotic syndrome in patients with AL, but the benefit is limited to patients achieving eradication of the plasma cell dyscrasia.[336] A randomized study was performed comparing autologous SCT with therapy with 2 cycles of oral melphalan and prednisone followed by SCT.[337] The OS of patients 1 year after randomization was higher for those who went directly to transplantation.

The role of tandem transplants and nonmyeloablative conditioning regimens has yet to be defined in this setting. Tandem transplantation has been reported in four patients, all with nephrotic syndrome.[338,339] Two died, one of sudden death and one, who had sepsis with GI tract bleeding, of complications of renal failure. Two of the patients are alive and in good health.

Patients who receive transplants for AL are highly selected on the basis of age, performance status, number of organs involved, absence of severe cardiomyopathy, and preserved renal function. Dispenzieri et al[340] reviewed an amyloidosis patient database to identify patients who might have been eligible for SCT. The inclusion criteria of biopsy-proven amyloidosis, symptoms of amyloidosis, absence of MM, restrictions on age, and adequate cardiac function led to the selection of 229 of 1288 patients. The median survival time of this group was 45 months, with 5- and 10-year survival rates of 36% and 15%, respectively (Fig. 87-21). Predictors of survival were size of the monoclonal protein component in the urine, number of organs involved (Fig. 87-22), serum alkaline phosphatase value, performance

Risk-Adapted Approach to Chemotherapy Dosing in Stem Cell Transplant Recipients

Good risk
- One or two organs involved
- No cardiac involvement
- Creatinine clearance ≥ 51 mL/min
- Any age

Intermediate risk
- Younger than 61 years old
- One or two organs involved
- Asymptomatic cardiac
- Or compensated cardiac
- Creatinine clearance <51 mL/min

Poor risk
- Three organs involved
- Advanced cardiac involvement

Melphalan dosing: as a function of risk group and age

Good Risk	*Intermediate Risk*	*Poor Risk*
200 mg/m^2 if ≤60	140 mg/m^2 if ≤50	Standard therapy
140 mg/m^2 if 61-70	100 mg/m^2 if 51-60	Clinical trials
100 mg/m^2 if ≥71

status, and weight loss. Being eligible for SCT but not actually receiving the transplant was associated with a better outcome than not being eligible for transplantation.

In summary, with appropriate patient selection, SCT is feasible but is associated with risks of higher morbidity and mortality than SCT for other disorders.

INVESTIGATIONAL THERAPIES

In an experimental model in which mice are injected with human AL proteins, amyloidomas result.[341a] When these animals receive injections of an anti–light-chain monoclonal antibody having specificity for an amyloid-related epitope, the amyloidomas rapidly resolve. This monoclonal antibody is directed toward a β-pleated sheet conformational epitope expressed by AL proteins. The amyloidolytic response appears to be associated with the release of proteolytic factors. AL resolution can be induced by passive administration of amyloid-reactive antibodies.[341a] This approach is currently under evaluation. A phase I exploratory investigational new drug study to determine the biodistribution of the fibril-reactive, amyloidolytic murine IgG1 mAb 11-1F4 labeled with I-124 was performed. Patients were infused with less than 1 mg (74 MBq) of GMP-grade antibody and imaged by positron emission tomography-computed tomography scan 48 and 120 hours later. Among nine of 18 subjects, there was striking uptake of the reagent in the liver; lymph nodes; BM; intestine; or, unexpectedly, spleen (but not kidneys or heart). Generally, positive or negative results correlated with those obtained immunohistochemically using diagnostic tissue biopsy specimens. Based on these findings,[124] I-mAb m11-1F4 can be used to identify AL candidates for passive immunotherapy using the chimeric form of the antibody.[341b]

Fourteen patients with AL received etanercept, an anti-TNF receptor monoclonal antibody, at 25 mg subcutaneously twice weekly.[342,343] Of 10 patients with adequate follow-up, two died and eight are stable. One patient had an improved septal wall thickness. Three patients experienced a 25% to 50% decrease in the degree of macroglossia. Two patients with diarrhea had significant improvement. In two of five patients with peripheral neuropathy, disease progression was halted with therapy. Only one patient had adverse effects. Larger studies to further evaluate the role of etanercept in the management of AL are warranted.[342]

Lacy et al[344] reported the use of a dendritic cell–based idiotype vaccination for AL. Ten patients were treated, and five had multiorgan AL. Three had received prior SCTs. One patient had an objective response, with proteinuria decreasing by 95%. One patient had improvement of painful peripheral neuropathy. Specific T-cell proliferative responses to idiotype were detectable in the patient who had a clinical response. Optimizing patients' immune function and response will be the subject of future studies.

Use of antisense oligonucleotides for the inhibition of amyloid immunoglobulin production has been explored.[345a] Antisense oligonucleotides against light-chain complementarity-determining regions prohibited light-chain production. It is possible to design specific complementary oligonucleotides, suggesting that treatment with antisense oligonucleotides could represent a rational approach to improve treatment outcomes in AL.[345a]

Serum amyloid P binds to all forms of amyloid deposits. Drugs have been developed that act as competitive inhibitors of serum amyloid P binding to amyloid fibrils.[52] Such compounds dimerize serum amyloid P molecules, leading to their rapid clearance by the liver and depletion of circulating serum amyloid P. Such agents remove serum amyloid P from human amyloid deposits and may destabilize the existing amyloid fibrils, allowing for their dissolution.[52] Such a therapeutic approach is of great interest. Administration of anti–human-SAP antibodies to mice with amyloid deposits containing human SAP triggers a potent, complement-dependent, macrophage-derived giant cell reaction that swiftly removes massive visceral amyloid deposits without adverse effects. Anti–SAP-antibody treatment is clinically feasible because circulating human SAP can be depleted in patients by the bis-d-proline compound CPHPC, thereby enabling injected anti-SAP antibodies to reach residual SAP in the amyloid deposits. The capacity of this combined therapy to eliminate amyloid deposits should be applicable to all forms of systemic and local amyloidosis.[345b]

DEFINING RESPONSES IN PRIMARY AMYLOIDOSIS

Responses to therapy in patients with AL can be defined by improved organ function or by hematologic responses comparable to those seen in patients with MM.[346a] All patients who have a measurable serum or urine monoclonal protein should be monitored for changes in the size of the monoclonal protein peak after any therapeutic intervention. For patients who have only a free light chain that cannot be quantified, immunofixation is used to determine if the protein is present or absent. The nephelometric free light-chain assay is extremely useful in monitoring patients serially to determine any decrease in circulating free light chain and has made the evaluation of response much easier.[41] FLC response is a more useful measure of hematologic response than M-protein response. It also highlights the importance of achieving at least a 90% reduction in the FLC-diff to improve the outcome of patients with light-chain AL.[346b]

The utility of the free light-chain assay in predicting outcome has been validated as noted earlier in this chapter, with 5-year survival rates of 88% for responders and 39% for nonresponders.[43] In the authors' experience, normalization of the free light-chain level was a better predictor of survival than was achievement of a complete hematologic response or normalization of the free light-chain ratio.[244] These results have been verified in a series of 25 patients with sequential free light-chain analyses.[347] All patients with a normalized κ to λ free light-chain ratio had a good prognosis.[347] The fraction of patients with serum-free light-chain responses has been suggested to be higher in patients receiving high-dose melphalan than in those who receive conventional therapy.[348]

Free light-chain responses also seem to parallel decreases in NT-pro-BNP levels in cardiac responders to therapy. For patients in whom free light chain decreased by more than 50%, the NT-pro-BNP concentration decreased by a median of 48%, but in patients without such a free light-chain decrease, the NT-pro-BNP concentration increased by 47%.[349] The NT-pro-BNP decrease was greater in complete responders than in other responders. The decrease of free light chains translates to a simultaneous decrease of NT-pro-BNP and improved survival. Cardiac function in AL can improve because of a

Table 87-6 Criteria for Amyloid-Related Organ Responses to Treatment*

Response	Progression
Heart	
Decrease of ≥2 mm in mean left ventricular wall thickness from baseline thickness >11 mm	Increase ≥2 mm in wall thickness
Two-class improvement in NYHA class	Two-class worsening in NYHA class
	NT-pro-BNP–based criteria were defined as a decrease or an increase of both >30% and >300 ng/L and a threshold of evaluability based on NT-pro-BNP baseline level >650 ng/L.
Kidneys	
>50% decrease in daily proteinuria without progressive renal insufficiency	>50% increase in daily proteinuria Progressive renal insufficiency
Liver	
A decrease in liver span of >50%	An increase in liver span of >25%
A concomitant decrease of alkaline phosphatase by 50%	An increase of alkaline phosphatase by 50%
Nervous System	
Autonomic: normalization of orthostatic vital signs and symptoms, resolution of gastric atony	Autonomic: progression of orthostatic vital signs and symptoms, increasing gastric atony
Peripheral neuropathy: resolution of symptoms	Peripheral neuropathy: progression of symptoms

NT-pro-BNP, N-terminal pro–brain natriuretic peptide; *NYHA,* New York Heart Association.
*If organ function neither improves nor worsens, it is graded as stable.

decrease in circulating amyloidogenic precursor despite the amount of cardiac amyloid deposits remaining unaltered as measured by echocardiography.[349]

Organ-based response criteria have been defined for patients with amyloid nephrotic syndrome (Table 87-6).[350] Requirements for definition as an "organ response" include a 50% decrease in the 24-hour albumin excretion without an increase in serum creatinine value. For hepatic involvement, a 50% decrease in an increased serum alkaline phosphatase concentration with no increase in liver size is required. Echocardiographic regression of amyloidosis is difficult to assess because of variability in estimates of the interventricular septal wall thickness. Typically, a decrease in septal thickness of at least 2 mm is required. Neurologic responses can be documented by EMG demonstrating improved nerve conduction velocities. A consensus panel has defined what constitutes organ involvement and treatment response in patients with AL.[350]

The consensus panel reconvened in 2010 to update hematologic and organ response criteria. The ability of response criteria to identify patients who died was compared by evaluating the areas under receiver operator characteristic curves based on death at 1 year and by calculating the Harrell C statistic and the Royston explained variation. The category of complete response (negative serum and urine immunofixation, normal FLC κ:λ ratio, and normal BM study results) was unchanged. With respect to cardiac response and progression, NT-pro-BNP–based criteria were defined as a decrease or an increase of both greater than 30% and greater than 300 ng/L, and a threshold of evaluability based on NT-pro-BNP baseline level greater than 650 ng/L was chosen.

The most powerful criteria for PR were those based on dFLC percent decrease, and a 50% cutoff was preferred because of easier clinical use. A definition of VGPR based on dFLC (<40 mg/L) was adopted.

FUTURE DIRECTIONS

Primary amyloidosis is a disease for which therapy remains inadequate. The diagnosis should be suspected whenever a patient is seen with unexplained nephrotic syndrome, heart failure, neuropathy, or hepatomegaly. The first screening test should be immunofixation of serum or urine and the free light-chain assay. If a monoclonal protein is found, BM biopsy and fat aspiration should be performed to obtain tissues for Congo red staining. The prognosis should be assessed by two-dimensional echocardiography and BNP and troponin level measurements. Monitoring therapy includes the use of immunoglobulin free light-chain assays by nephelometry and cardiac biomarkers. Systemic chemotherapy is appropriate for most patients. SCT should be strongly considered if patients fulfill eligibility criteria. The use of solid organ transplantation remains investigational. The ideal treatment of patients with AL remains unknown, but early diagnosis is essential to ensure superior outcome.

CHAPTER 88

CLINICAL APPROACH TO INFECTIONS IN THE COMPROMISED HOST

Samuel A. Shelburne, Russell E. Lewis, and Dimitrios P. Kontoyiannis

Advances in the supportive care and treatment of hematologic malignancies have markedly improved the life expectancy of afflicted patients, but this progress is increasingly at the expense of developing a wider range of infectious complications often caused by drug-resistant organisms. The clinical approach to infections occurring among hematology patients involves understanding host immune system defects and anatomic barrier disruption that predispose patients to infection (Fig. 88-1). This chapter reviews specific hematologic conditions for their unique host defense defects and associated infections (Table 88-1) and the differential diagnoses of common infectious pathogens (Table 88-2). To demonstrate how periods of predictable anatomic defects combine with severe immune compromise, the prevention, diagnosis, and management strategies for infections occurring in the hematopoietic stem cell transplant (HSCT) recipient are presented as models.[1]

HEMATOLOGIC CONDITIONS PREDISPOSING TO INFECTION

Malignant Hematologic Disorders

Antineoplastic Therapy

During antineoplastic treatment, cytotoxic agents frequently are administered in combination with other immunosuppressive therapies, such as corticosteroids or radiation therapy. Several cytotoxic agents, notably methotrexate, cyclophosphamide, 6-mercaptopurine, and azathioprine, impair cell-mediated immunity. Many of the drugs themselves (e.g., cyclophosphamide) also impair humoral responses and produce quantitative phagocyte defects. Fludarabine, the major first-line therapy for chronic lymphocytic leukemia (CLL), can produce prolonged and profound defects in cell-mediated immunity, thereby increasing susceptibility to *Pneumocystis,* yeast, and herpes group viruses (herpes simplex virus [HSV], varicella-zoster virus [VZV], and cytomegalovirus [CMV]).

The use of monoclonal antibody therapy for hematologic disorders results in dysfunction of particular aspects of the immune system.[2] Rituximab results in a sustained depletion of B lymphocytes for 6 to 9 months and has been specifically associated with reactivation of hepatitis B virus infection.[3] Alemtuzumab administration causes profound lymphopenia and an increased risk for a variety of viral and fungal infections.

Exogenous administration of glucocorticoids leads to increased susceptibility to infection. The degree of immunosuppression and the relative risk for infection depend on the dose and duration of use. The major effect of steroids on granulocyte function is a decrease in chemotactic activity. This accounts, in part, for the clinical observation that the signs and symptoms of severe infections may be masked or greatly reduced in patients receiving steroids. Steroids may enhance susceptibility to infection by means of negative effects on glucose homeostasis, wound healing, skin fragility, monocyte and lymphocyte function, production of cytokines, and humoral immune responses.

Radiation therapy has been associated with granulocyte dysfunction and delayed wound healing. Defects in cell-mediated immunity may persist for more than 1 year after intensive radiation therapy or after HSCT.

Acute Leukemias

In patients with acute leukemias, a major cause of morbidity is infection due to drug-associated mucositis and therapy-induced neutropenia. Most infections occurring during neutropenia are bacterial, but patients with prolonged neutropenia are at additional risk for development of yeast and mold infections. Patients with acute leukemia who progress to advanced therapies, such as hematopoietic cell transplant, have added risk for infections associated with acquired deficiencies in cell-mediated and humoral immunity, such as *Pneumocystis jiroveci* and CMV infections.[1]

Chronic Leukemias

Patients with chronic myeloid leukemia do not have prominent host defense impairments, so infections are limited unless patients proceed to aggressive chemotherapy or HSCT. Host defense defects with tyrosine kinase inhibitors, such as imatinib or dasatinib, have not been well defined. Chemotherapy for blast crisis resembles therapy for acute leukemia. Patients with chronic lymphocytic leukemia (CLL) are predisposed to infection because of immunodeficiency related to the leukemia itself (humoral and cellular immune dysfunction) and to therapy-related immunosuppression.[4] In early B-cell CLL, the infectious risk is mainly related to unbalanced immunoglobulin chain synthesis and resultant hypogammaglobulinemia. In patients with advanced CLL, particularly after the introduction of therapy with purine analogues and monoclonal agents (e.g., rituximab, alemtuzumab), neutropenia and defects in cell-mediated immunity are other factors predisposing to infection. The risk for infectious complications increases with the duration of CLL, reflecting the cumulative immunosuppression related to its treatment. The incidence of infection correlates with the serum levels of immunoglobulins (particularly IgG), which may be further impaired by use of rituximab.

Lymphomas

Hodgkin and non-Hodgkin lymphoma are commonly associated with impaired cell-mediated immunity. The degree of immune impairment may correlate with the extent of disease and often is compounded by administration of immunosuppressive therapy.[3] The intrinsic impairment of cell-mediated immunity in Hodgkin lymphoma can persist even after apparent cure. Splenectomy-related infections occur with sepsis caused by encapsulated bacterial organisms at a median of 22 months but sometimes many years after surgery.

Myelodysplastic Syndrome

Neutrophils and band forms from patients with myelodysplastic syndrome are functionally defective and probably are derived from a

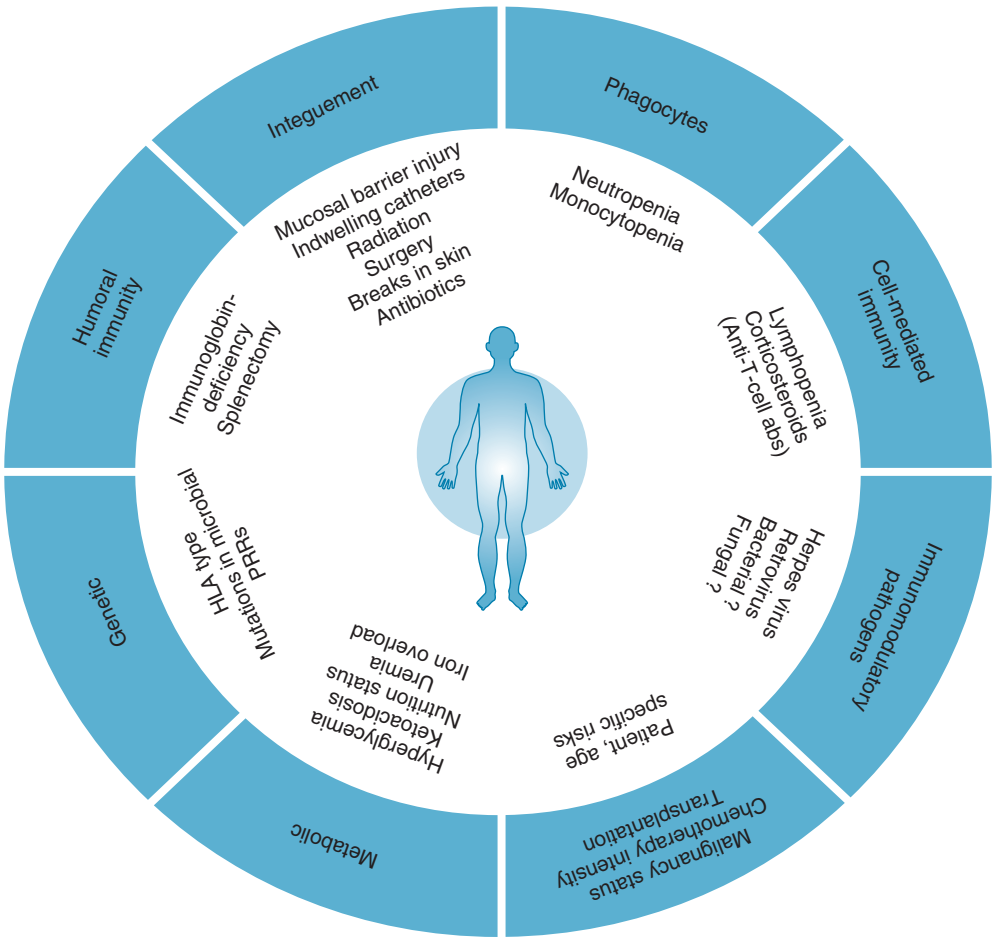

Figure 88-1 CONSTELLATION OF FACTORS CONTRIBUTING TO INCREASED RISK FOR INFECTION IN IMMUNOCOMPROMISED HOSTS.

malignant clone of myeloid precursor cells. Neutrophils from patients with myelodysplastic syndrome have deficiencies in myeloperoxidase, elastase, and integrins. More than half of patients with myelodysplastic syndrome die within 3 years of diagnosis from infections, bleeding complications, or progression to acute leukemia.

Multiple Myeloma

Malignant plasma cells produce a variety of immunomodulatory molecules such as TGF-B which suppress B-cell function, so multiple myeloma is frequently associated with a variety of defects in humoral immunity.[5] Patients having myeloma with IgG paraprotein have an increased rate of catabolism of normal and clonal IgG. They also may have defects in complement and granulocyte function. Cell-mediated immunity is not impaired by the disease but is compromised by corticosteroids or cytotoxic therapy.

Uncommon Malignancies

Patients with hairy cell leukemia develop mycobacterial disease relatively often, especially infection with atypical mycobacteria. Reversal of host cellular immune defects with effective therapy can lead to rapid clinical response with eradication of mycobacterial infection.

Defects in cell-mediated immunity have been postulated to explain the incidence of infection caused by intracellular pathogens in patients with the relatively rare T-cell malignancies mycosis fungoides and T-cell CLL.

Nonmalignant Hematologic Disorders

Aplastic Anemia

This blood dyscrasia is associated with decreased peripheral blood cell counts due to marrow failure. Chronic neutropenia is the main cause of recurrent bacterial and fungal infections among patients. Periodontal infections are particularly common. Treatment of the underlying hematologic disease is required to stop recurrent infections and cure some chronic infections.

Paroxysmal Nocturnal Hemoglobinuria

Patients with paroxysmal nocturnal hemoglobinuria are at some increased risk for bacterial infection due to a deficiency of decay-accelerating factor on the membrane of neutrophils. Modest and progressive granulocytopenia, progression to aplasia or leukemia may compound these risks. Vaccination against meningococcus is required before treatment with the terminal complement inhibitor eculizumab.

Granulocytic Phagocyte Disorders

The clinical approach to infections in patients with granulocytic phagocyte disorders is specific to each of these disorders and is beyond the scope of this chapter. However, chronic granulomatous disease is discussed because patients with this congenital immunodeficiency

Table 88-1 Malignant and Select Nonmalignant Hematologic Diseases and Their Associated Infection-Predisposing Host Defects

Hematologic Condition	Infection-Predisposing Host Defects
Acute myeloid leukemia	Neutropenia; therapies such as dose-intensive chemotherapy and hematopoietic stem cell transplant may result in additional anatomic disruptions, cell-mediated defects, and humoral defects
Acute lymphocytic leukemia	Neutropenia; therapy effects similar to acute myeloid leukemia
Hairy cell leukemia	Neutropenia (also monocytopenia); abnormal humoral immunity; T-cell suppressing therapy
Chronic lymphocytic leukemia	Hypogammaglobulinemia; abnormal cell-mediated immunity
Chronic myeloid leukemia	No prominent host defects unless aggressive therapy, advanced stage, or postsplenectomy
Multiple myeloma	Hypogammaglobulinemia; other host defects may occur with aggressive therapy or advanced stage
Hodgkin/non-Hodgkin lymphomas	Abnormal cell-mediated immunity, therapy-related neutropenia, splenic dysfunction (if splenectomy or radiation)
Myelodysplastic syndromes	Functional or absolute neutropenia
Aplastic anemia	Neutropenia; abnormal cell-mediated immunity from immunosuppressive therapies (e.g., steroids, antithymocyte globulin, cyclosporine, hematopoietic stem cell transplantation)
Paroxysmal nocturnal hemoglobinuria	Deficient Fc receptor may contribute to abnormal cell-mediated immunity
Hemolytic states (thalassemia)	Gallstones may serve as a nidus for infection; splenic dysfunction or splenectomy
Sickle cell disease	Can be neutropenic with aplastic crisis; bone infarcts may serve as a nidus for infection; splenic dysfunction with poor complement activation and opsonization from autosplenectomy

who survive into adulthood are at risk for severe infections. Chronic granulomatous disease is a heterogeneous group of disorders resulting from defective or malfunctioning oxidative metabolism capacity of phagocytes. Recurrent infections with bacteria and fungi are common and occasionally life threatening, despite optimal antimicrobial therapy. Infections with *Staphylococcus* species and *Aspergillus* species can be particularly aggressive.[6] Granulomata may form in response to infection, especially in the gastrointestinal and genitourinary tracts.

Erythrocyte Disorders

Glucose-6-phosphate dehydrogenase deficiency is a sex-linked disorder. Deficiency of this enzyme limits glucose metabolism through the hexose monophosphate shunt, resulting in an abnormal respiratory burst in neutrophils. Bacterial infections can occur if the deficiency is severe.

Hemoglobin Gene Variants

Patients with chronic hemolytic states may develop bilirubin gallstones, which can serve as a nidus for infection. Defects

Table 88-2 Host Defense Impairments and Their Associated Infectious Pathogens

Host Defense Defect	Pathogen Categories
Neutropenia	Enteric gram-negative organisms Gram-positive staphylococci and streptococci Anaerobes Yeast, particularly *Candida* species Molds, particularly *Aspergillus* species
Abnormal cell-mediated immunity	Atypical bacteria: *Legionella, Nocardia* *Salmonella* species *Mycobacteria* (*M. tuberculosis* and atypical mycobacteria) Disseminated infection from live bacilli Calmette-Guérin (BCG) vaccine Environmental fungi, including *Cryptococcus neoformans, Histoplasma capsulatum, Coccidioides immitis* Endogenous yeast, particularly *Candida* species Herpesviruses Infections from live-virus vaccines *Pneumocystis iroveci* *Toxoplasma gondii* *Cryptosporidium* *Strongyloides stercoralis*
Immunoglobulin abnormalities	Gram-positive *Streptococcus pneumoniae, Staphylococcus aureus* Gram-negative *Haemophilus influenzae*, *Neisseria* species, enteric organisms Enteroviruses Disseminated infections from live-virus vaccines *Giardia lamblia*
Complement abnormalities C3, C5	Gram-positive *S. pneumoniae*, staphylococci Gram-negative *H. influenzae, Neisseria* species, enteric organisms
Complement abnormalities C5–C9	*Neisseria* species
Anatomic Disruption	Pathogen Categories
Oral cavity	α-Hemolytic streptococci, oral anaerobes *Candida* species Herpes simplex virus
Esophagus	*Candida* species, Herpes simplex virus, cytomegalovirus
Lower gastrointestinal tract	Enterococcus, gram-negative enteric organisms, Anaerobes *(Bacteroides fragilis, Clostridium perfringens),* *Candida* species, *Strongyloides stercoralis*
Skin (IV catheter)	Gram-positive staphylococci and streptococci, *Corynebacteria, Bacillus,* Atypical mycobacteria
Urinary tract	Enterococcus, Gram-negative enteric organisms *Candida* species
Splenectomy	Encapsulated organisms: *S. pneumoniae, H. influenzae, Neisseria, Capnocytophaga canimorsus* *Salmonella* (especially sickle cell disease), *Babesia*

in cell-mediated immunity have been described in patients with thalassemia. Patients with sickle cell disease have an increased susceptibility to bacterial infections.[7] Defective alternative complement pathway function, especially in conjunction with asplenia, contributes to the propensity to bacterial infection. Splenic involution results in depressed synthesis of alternate pathway factor(s) of complement and decreased phagocytic clearance of bacteria. Phagocytosis of *Streptococcus pneumoniae* is abnormal, in part because of an inability to use the alternate pathway for C3 fixation as a means of opsonization. An increased risk for *Salmonella* infection appears to be unique to the sickle cell population. Suppurative arthritis can occur after repeated episodes of hemarthrosis among patients with sickle cell disease.

Coagulation Disorders

Hemophilias are sex-linked deficiencies of clotting factor VIII or IX. Septic arthritis should be considered in the differential diagnosis of any hemophiliac with repeated episodes of hemarthrosis whose articular signs and symptoms fail to improve quickly after administration of appropriate coagulation factor replacement. Hemophiliacs who have acquired infection with human immunodeficiency virus (HIV)-1 from plasma-derived factor replacement therapy may develop severe impairment of cell-mediated immunity after this retroviral infection progresses to acquired immunodeficiency syndrome (AIDS).

Blood Groups

The Duffy blood group antigen serves as a receptor for *Plasmodium vivax* to invade erythrocytes. Blood group O is associated with *Helicobacter pylori* infection and an associated increase in peptic ulceration because the Lewis(b) blood group antigen mediates *H. pylori* attachment to human gastric mucosa.

Host Defense Impairment and Associated Infection Issues

Neutropenia

Profound or absolute neutropenia can occur in patients with aplastic anemia or leukemia or from chemotherapy used for treatment of various malignant diseases. Infection rates increase when neutrophil counts fall below 1000/mm^3, but the patient is most at risk for spontaneous infection when the count is below 100/mm (Fig. 88-2). The patient who is neutropenic from cytotoxic therapy can serve as a basic model for predicting infections that could occur in other patients with qualitative or quantitative granulocyte defects.

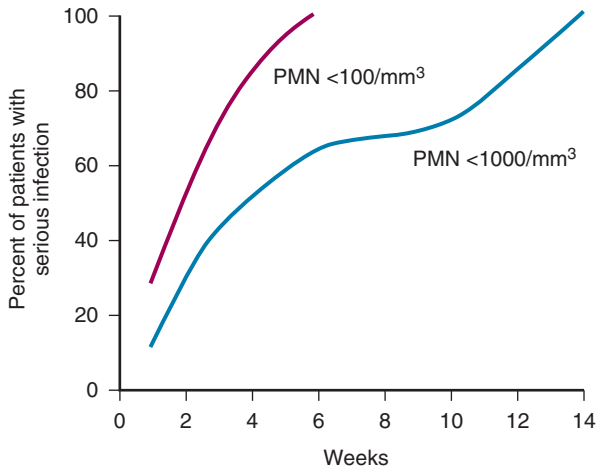

Figure 88-2 RELATIONSHIP OF SEVERITY AND DURATION OF NEUTROPENIA TO THE RISK FOR DEVELOPING A SERIOUS INFECTION. *(Courtesy GE Body.)*

Neutropenia predisposes to the development of bacterial and fungal infections but does not appear to increase the incidence or severity of viral and parasitic infections. Patients with profound and prolonged neutropenia who are at particular high risk for infection (e.g., cytopenic patients with acute myelogenous leukemia and severe mucositis following induction therapy) are likely to benefit from receiving prophylactic antimicrobials.[8,9] However, patients with moderate granulocytopenia (i.e., absolute granulocyte counts in the range from 500 to 2000/mm^3 that are not falling precipitously) should not receive prophylactic antimicrobial agents. Colony-stimulating factors (granulocyte colony-stimulating factor [G-CSF; pegylated filgrastim], granulocyte-macrophage colony-stimulating factor [GM-CSF, sargramostim]) are routinely used in the management of hematologic disorders. A number of functional granulocyte parameters may be enhanced by G-CSF or GM-CSF, including enhanced per-cell phagocytosis, oxidative metabolism, microbicidal activity, and antibody-dependent cytotoxicity.[10] However, G-CSF or GM-CSF administration may decrease the motility of granulocytes, impair in vivo migration, and decrease bacteria-induced chemotaxis. The clinical significance of any of these effects remains to be established but is generally believed to be insignificant in light of the potency of these agents in shortening the depth and duration of therapy-induced neutropenia.

Defects in Cell-Mediated Immunity

Cellular immune dysfunction occurs in patients with lymphoid malignancies, in those with hematologic malignancies undergoing HSCT, and in patients with AIDS. The most frequently encountered pathogens are intracellular organisms because they can survive and even replicate inside macrophages in a nonimmune individual or in the absence of T-cell immunity. Specific pathogens associated with infection in patients with cell-mediated immunity include bacteria (including *Mycobacterium tuberculosis,* atypical mycobacteria, *Salmonella,* streptococci, *Legionella, Nocardia,* and *Listeria*); fungi (including the yeasts *Candida* and *Cryptococcus;* molds such as *Aspergillus;* endemic dimorphic fungi such as *Histoplasma* and *Coccidioides;* and *Pneumocystis*); viruses (including herpes group viruses [HSV, VZV, CMV] and respiratory viruses); and protozoa (*Toxoplasma gondii, Cryptosporidium,* and *Strongyloides stercoralis*).

Patients with defects in cell-mediated immunity or who are about to receive HSCT should undergo risk factor assessment for reactivation of tuberculosis. Patients with a known history of an untreated but positive Mantoux test or interferon-gamma release assay should receive prophylactic isoniazid to prevent reactivation and potential dissemination of tuberculosis. Patients without a prior Mantoux test but with risk factors for tuberculosis should undergo a screening test for latent tuberculosis before starting the conditioning regimen for HSCT.

Patients with defects in cell-mediated immunity are at risk for the development of disseminated infection due to live vaccines, even when the vaccine contains attenuated organisms. Accordingly, these patients should not receive vaccines containing bacillus Calmette-Guérin (BCG), vaccinia/smallpox, measles, mumps, rubella, yellow fever, or oral polio.[11] HSCT recipients are eligible for revaccination with some of the live virus vaccines 2 years after transplantation, provided the patient does not have graft-versus-host disease (GVHD) or is not receiving ongoing pharmacologic immunosuppression (see Chapter 110, Table 110-4).

Defects in the Humoral Immune System

Immunoglobulin and complement are components of the humoral immune system. Immunoglobulin and complement both have associated lytic and neutralizing activities. Patients with primary or secondary defects or deficiencies in humoral immunity are susceptible to

recurrent pyogenic infections from polysaccharide-encapsulated bacteria, such as *Streptococcus pneumoniae, Haemophilus influenzae,* and *Neisseria* species. HSCT recipients who continue to receive immunosuppressants more than 100 days after transplantation should be given antimicrobial prophylaxis with coverage for encapsulated bacteria until immunosuppression is discontinued. Patients are also at risk for infections from enteroviruses and *Giardia lamblia*. Patients with low levels of circulating IgG may benefit from intravenous Ig (IVIg) infusions, although the benefit of using of IVIg infusions for routine prophylaxis must be weighed against the expense of this approach.

Abnormalities in Splenic Function

A number of hematologic disorders are complicated by either intrinsic splenic impairment or splenectomy. The spleen removes organisms from the blood that have been ineffectively opsonized by complement, serving an adjunctive role in fighting infection. It is involved in the regulation of the alternate complement pathway, and low levels of immunoglobulin and properdin have been reported in patients after splenectomy. Alternate pathway defects may be particularly important in patients with splenic dysfunction associated with sickle cell disease.

Asplenic or splenectomized patients are at increased risk for serious, frequently fulminant, bacterial infections, primarily for infections caused by *S. pneumoniae, H. influenzae, Neisseria, Babesia*, and *Capnocytophaga canimorsus*. The initial presentation of even overwhelming infection can be subtle, with fever often the only sign. Accordingly, all asplenic patients with underlying hematologic disease who present with fever should be managed initially as potentially septic. Overwhelming infection after splenectomy occurs in approximately 7% of postsplenectomy patients, with 50% of infection-related deaths occurring in the first 3 months. Prophylaxis against pneumococcal infection is used for asplenic patients who are small children or for those with increased immune impairment from malignant disease.

Pneumococcal, *H. influenzae* type b, and meningococcal vaccines should be administered to asplenic patients. Patients with an intact spleen may respond better to pneumococcal polysaccharide vaccine than do splenectomized patients, so immunization is recommended as early as possible before elective surgery. Additionally, immunization before splenectomy can result in protective pneumococcal antibody titers immediately after the operation. For patients with Hodgkin lymphoma, the antibody response to pneumococcal vaccine may not be affected by the timing of immunization relative to splenectomy. Immunizations reduce, but do not eliminate the risk for serious infection with encapsulated bacteria.

Anatomic Alterations in Host Defense

Immunocompromised patients frequently have disruptions in the skin and mucosa, which are important primary physical barriers against endogenous and exogenous sources of infections (Fig. 88-1). Disruption of skin and mucosa may result from invasion by malignant cells, from the effects of chemotherapy or radiation therapy, from use of invasive diagnostic or therapeutic procedures (e.g., intravenous catheters), and from the effects of local infections, such as oral HSV. Such alterations may provide a nidus for microbial colonization, a focus for localized infection, and a portal of entry for systemic invasion. Organisms associated with defects in skin or mucosal surfaces depend on the site of breakdown, local colonizing flora, and other factors. Gram-positive organisms are associated with isolated disruption of the skin from an indwelling intravenous catheter, usually with coagulase-negative staphylococci, but also with *Corynebacterium jeikeium, Bacillus* species, and occasionally atypical mycobacteria.

Gastrointestinal mucosal integrity is frequently disrupted by chemotherapeutic agents. Because the gastrointestinal tract normally is colonized by a multitude of organisms, this state can lead to infection by streptococci, aerobic gram-negative enteric and anaerobic bacteria, and yeast. Mucosal damage can allow normal flora to invade and become pathogens. Lower gastrointestinal ulcerations permit infections by *Bacteroides fragilis* or *Streptococcus bovis*. Oral lesions are associated with HSV reactivation, ulceration, and possible bloodstream infection with other common oral flora such as α-hemolytic streptococci.

The genitourinary tract mucosa may be disrupted by tumors, invasive procedures, or cytotoxic therapy, with subsequent colonization and the potential for local or invasive infection. The most common urinary tract pathogens are enteric gram-negative bacilli, enterococci, and *Candida albicans*. Viral reactivation is common, predominantly from adenovirus and polyomavirus (BK virus), but also from the herpesviruses (HSV and CMV).

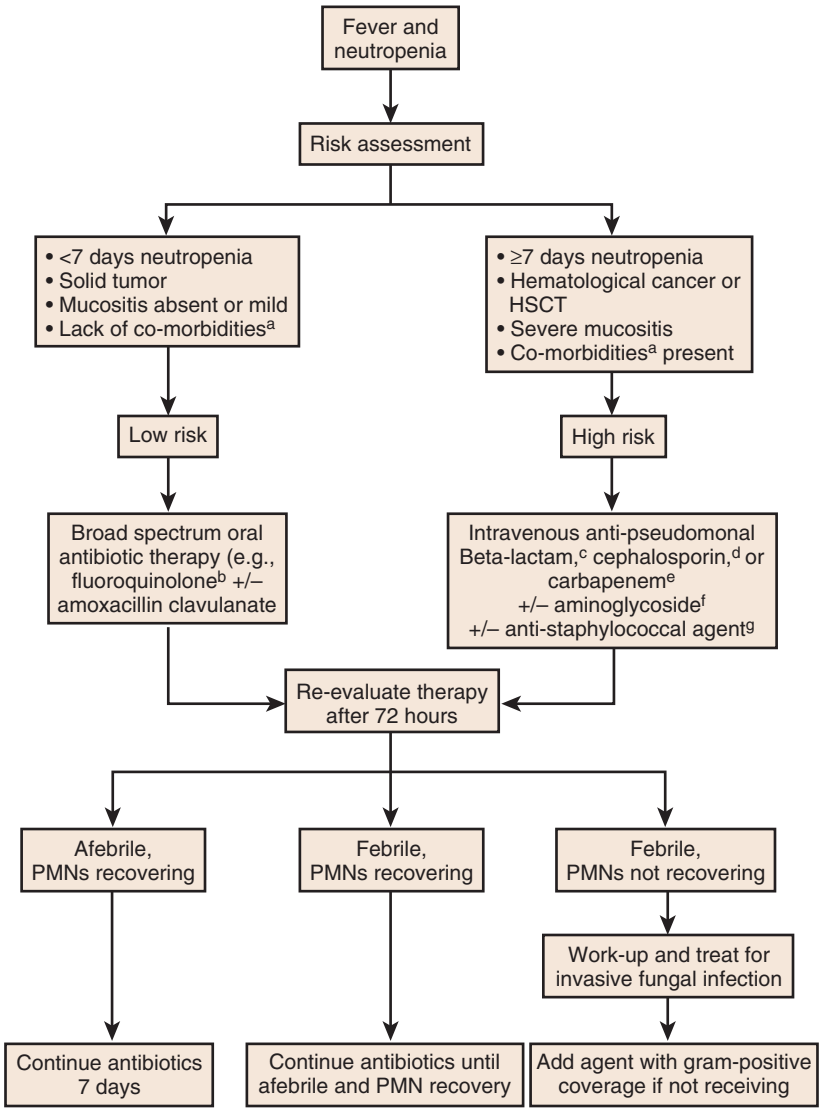
The lung, genitourinary tract, biliary tract, and auditory canal are potential sites of mechanical obstruction, increasing the risk for localized infection. Obstruction may lead to stasis of local body fluids, with resultant overgrowth of potentially pathogenic colonizing organisms. Patients with chronic hemolytic states are prone to gallstones that can become a nidus for infection.

Anatomic alteration can predispose to infection simply by providing a nidus for growth of organisms. Many patients with sickle cell anemia and hemophilia have underlying anatomic abnormalities of the bones and joints as a result of vasoocclusive crises causing infarction of marrow, bony cortex, or synovium. In turn, these changes may predispose to infection such as osteomyelitis or arthritis. Decreased local blood flow and increased bacterial adherence may be other contributing factors. Foreign bodies, such as prosthetic devices, can lead to persistent infection after even transient bacteremia.

Infection in Patients With Acute Neutropenia or Lymphopenia Following Chemotherapy or Transplantation

This section outlines predictable infections that can present during acute profound neutropenia/lymphopenia.

Fever



Despite the specific prophylactic measures directed against common pathogens, many fevers occur in neutropenic patients after transplantation or chemotherapy. Fever can be divided into three categories: infectious fever with an obvious source, infectious fever without an obvious source, and noninfectious fever. Risk factor assessment should include knowledge of the temporal relationship to blood product infusions; recent exposure to contagious infection; degree of fever and whether the fever is accompanied by chills, rigors, or diaphoresis; and response to antipyretics. Symptom assessment should include evaluation to assess sinus drainage, sore throat, ear pain, cough, sputum production, shortness of breath, abdominal pain, diarrhea, rash, and dysuria.

The initial workup of fever in a patient with neutropenia, regardless of whether an infectious or noninfectious source is suspected, is identical and includes blood culture, culture of symptom-related sites even if there is no obvious source (e.g., sputum, urine, with/without stool, with/without cerebrospinal fluid), review of medication list for potential contributors to drug fever, review of recent transfusions, chest radiograph, and CT scan of any symptom-related body systems. When feasible, blood cultures should be drawn through an existing indwelling catheter as well as peripherally because this can facilitate the diagnosis of a catheter-related bloodstream infection compared with a bloodstream infection arising from a different source (e.g., the GI tract).[12]

Consensus guidelines on the management of patients with febrile neutropenia have been published.[13] Empiric antibiotics are recommended for all febrile patients with neutropenia, but the type of

antibiotics and the site of administration (i.e., hospital vs. outpatient) depends on the severity of immunosuppression, expected duration of neutropenia, and factors related to the local epidemiology and resistance patterns (Fig. 88-3). Patients defined as low-risk using the Multinational Association for Supportive Care in Cancer (MASCC) index can be treated as outpatients, whereas other patients are generally admitted for intravenous therapy.[14] Typical pathogens causing infection in this situation include *Enterobacteriacae, Pseudomonas, Streptococcus,* and *Staphylococcus* spp. Thus antipseudomonal β-lactam antibiotics such as third-generation cephalosporins, piperacillin-tazobactam, and carbapenems are commonly employed as empiric therapy.[15] Vancomycin is administered if staphylococcal disease is suspected or if the patient is clinically unstable while cultures are pending. Severely ill patients are often also treated with an aminoglycoside for the first 48 to 72 hours of illness, although data in support of this approach are lacking.

Therapeutic changes to the antimicrobial regimens are made in response to culture results, but the cultures are negative about 50% of the time (Fig. 88-3). If the patient becomes afebrile, therapy is usually continued for 7 days. Persistent fever after more than 72 hours of empiric therapy suggests an untreated infection. An agent with activity against resistant gram-positive organisms (e.g., vancomycin) should be added at this point if one was not begun initially. If the patient is recovering his or her neutrophil count, no additional changes in antibiotics are typically needed. However, the persistently neutropenic and febrile patient may have an occult fungal infection such as candidiasis or aspergillosis. Thus initiation of empiric antifungal therapy with antimold activity (e.g.,

[a] Hypotension, altered mental status, neurologic changes, respiratory failure, abdominal pain, hemorrhage, cardica compromise or new arrythmia, catheter tunnel infection, extensive cellulitis, acute renal or liver failure
[b] Institution sensitivity dependent, ciprofloxacin, levofloxacin, moxifloxacin
[c] Drug selection and dosing institution-specific: piperacillin tazobactam, ticarcillin/clavulanate
[d] Drug selection and dosing institution-specific: ceftazidime, cefepime, [e]imipenem/cilastatin, meropenem, doripenem
[f] Gentamin, tobramycin, or amakacin
[g] Drug selection and instituion institutio-specfic: vancomycin, linezolid, daptomycin, ceftaroline

Figure 88-3 APPROACH TO PATIENT WITH FEVER AND NEUTROPENIA.

Table 88-3 Pulmonary Infiltrates and Their Association With Specific Infectious and Noninfectious Etiologies

Radiologic Sign	Differential Diagnosis
Interstitial infiltrates	Pulmonary edema Diffuse alveolar damage Idiopathic pneumonia syndrome Respiratory viruses: respiratory syncytial virus, parainfluenza, influenza, adenovirus, enterovirus Herpes viruses: cytomegalovirus, herpes simplex virus, varicella zoster virus, human herpes virus type 6 *Pneumocystis* pneumonia
Focal airspace disease	Bacterial pneumonia Fungal pneumonia
Nodules	Fungal pneumonia (aspergillosis) *Nocardia* *Legionella* Septic bacterial emboli Mycobacterial infection (with cavitation) Epstein-Barr virus lymphoproliferative disorder Relapsed malignancy Pulmonary embolism (pleural based)
Halo sign or air crescent sign	Aspergillosis

amphotericin B, caspofungin, voriconazole) is usually begun in such a situation.

Two common anaerobic infections occur during neutropenia at sites where biopsy is difficult or contraindicated. Neutropenic enterocolitis, also known as typhlitis, manifests as fever, abdominal pain, and tenderness. CT scan of the abdomen shows signs of right-sided colonic and ileal inflammation.[16] Excessive soft-tissue swelling of the neck during mucositis can present as a Ludwig angina variant. Broadly active antianaerobic, aerobic, and possibly antifungal antimicrobial agents should be added for either of these clinical findings.

Pulmonary Infiltrates

Pulmonary infections are common in the immunocompromised host (see box on Approach to Pulmonary Infiltrates). Plain chest radiography is a good initial screen but lacks the sensitivity of computerized tomography (CT), which generally provides more useful information in terms of characterizing the nature of an infiltrate and assists the pulmonologist in determining where to direct the bronchoscope for highest yield. A specific infectious and noninfectious differential diagnosis exists for certain radiologic signs (Table 88-3). For example, consolidative focal airspace disease is associated most typically with a bacterial pneumonia. A halo of interstitial changes around a pulmonary nodule or an air crescent above a pulmonary nodule is most likely due to aspergillosis (Fig. 88-4).[17] Although 90% of pulmonary nodules are due to fungal pneumonia (mainly aspergillosis), 10% have various etiologies, including septic bacterial emboli, *Nocardia, Legionella,* mycobacterial infection (with cavitation), Epstein-Barr virus (EBV)–related lymphoproliferative disease, relapsed malignancy, and pulmonary embolism (pleural based). Interstitial infiltrates can be caused by either respiratory viruses during the winter season (except for parainfluenza virus, which is nonseasonal), herpes viruses, *Pneumocystis,* edema, or idiopathic. A complete differential of causes of interstitial pneumonitis (a pulmonary syndrome often associated with HSCT) is given in Chapter 110.

Pulmonary and sinus infections from inhaled molds are more likely to occur as the duration of neutropenia lengthens, particularly beyond an initial 21-day window. For that reason, among HSCT recipients without graft failure, invasive tissue mold infections occur at a low rate (less than 3%) before engraftment because of the environmental preventive measures taken for air filtration. However, if endogenous occult aspergillosis infections are present before HSCT, the infection can rapidly escalate when the immune system is profoundly suppressed by the preparative regimen. This phenomenon manifests as early invasive aspergillosis (before day 40). Therefore patients with hematologic malignancy at risk for occult mold infections in the lungs, sinuses, and at times, the oral cavity should have CT scans of the lungs and sinuses before the onset of any profoundly immunosuppressive regimens, such as HSCT and select nontransplantation regimens. High-risk patients may be given mold-active

Approach to Pulmonary Infiltrates

Pulmonary infiltrates can be divided into three general categories: consolidative, interstitial, and nodular. A consolidative infiltrate may be bacterial, even polymicrobic, so sampling of the infiltrate through sputum or endotracheal tube suctioning for bacterial and fungal cultures is required. If either of these methods does not provide an adequate sample from a consolidative infiltrate, or if these methods do not lead to a diagnosis, "early" (within 72 hours) bronchoscopy is indicated. If interstitial or nodular infiltrates are not peripheral (i.e., within the range of the bronchoscope), they should also be evaluated with timely bronchoscopy. An advantage of bronchoscopy, in addition to the ability to obtain a deep specimen, is that the samples usually are sent for a broad range of diagnostic tests. These tests usually are ordered from preprinted order sheets, which reduce errors. Most preprinted order sheets for bronchoalveolar lavage fluid will test for the following:

- Cytology, with the attendant Fite and Gomori methenamine silver stains
- Bacterial (Gram) stain and aerobic culture
- Mycobacterial (acid-fast bacillus) stain and culture
- Fungal (potassium hydroxide or calcofluor) stain and culture
- *Nocardia* culture
- *Legionella* culture
- Viral cultures for herpes viruses and respiratory viruses
- Rapid test for cytomegalovirus (shell vial or polymerase chain reaction [PCR])
- Rapid test for respiratory viruses during respiratory virus season (pooled respiratory virus shell vial, respiratory syncytial virus antigen, influenza A/B antigen)

Optional tests that can be requested from bronchoalveolar lavage fluid, some at significant extra expense, include the following:

- Mycobacterial stain (requires separate 5-mL volume that cannot be used later for culture)
- *Mycoplasma pneumoniae* PCR
- *Chlamydia pneumoniae* PCR
- Human herpes virus type 6 PCR
- Human metapneumovirus PCR
- *Aspergillus* galactomannan antigen
- Any of the above first-tier tests that your institution does not send on a routine basis (e.g., *Nocardia* or *Legionella*)

Invasive sampling may be the only definitive means for making a diagnosis of peripheral nodules. The two main options are percutaneous fine-needle aspiration or open lung biopsy (usually obtained through video-assisted thoracoscopic surgical procedure). In toto sampling of a lung nodule permits enough material for the whole range of the above diagnostic tests as well as histopathology. Of note, fewer lobectomies of unilateral pulmonary nodular infiltrates have been reported in recent years, probably a result of the frequent use of a broad range of less toxic antifungal medications.

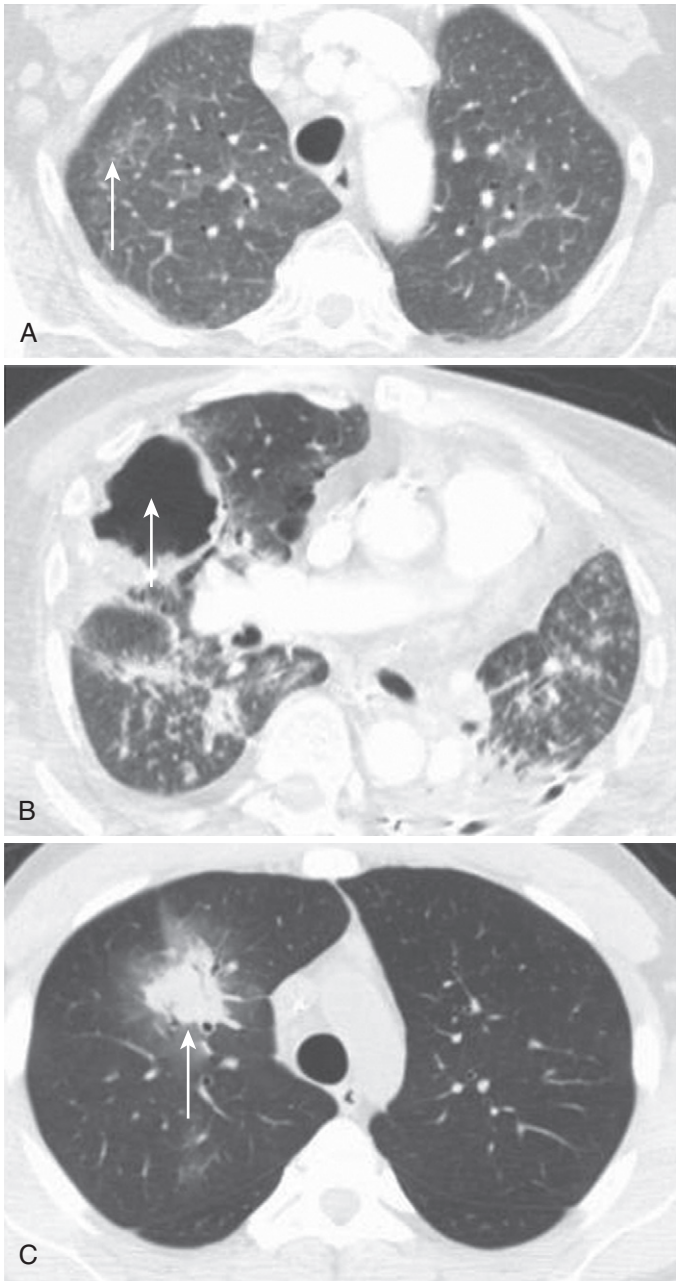


Figure 88-4 CT SCAN EXAMPLES OF DIFFERENT PULMONARY INFILTRATES IN IMMUNOCOMPROMISED PATIENTS. **A,** Diffuse ground-glass opacities in a patient with *Pneumocystis jiroveci* pneumonia. **B,** Cavitary lung lesion in a patient with *Pseudomonas aureginosa* pneumonia. **C,** Lung nodule with halo sign due to *Aspergillus*. For each panel, the *arrow* points to involved pulmonary parenchyma.

antifungal prophylaxis to either prevent or suppress invasive mold infections.

Bacteria

Because bacterial infections cause significant morbidity and mortality in neutropenic patients, broad-spectrum antibacterial prophylaxis is often used during periods of profound neutropenia. The exact agents used vary, but typical agents include a quinolone (e.g., levofloxacin) or a β-lactam (e.g., cefpodoxime). Institutional protocols and resistance patterns drive selection of specific prophylactic agents. Oral prophylaxis regimens are generally discontinued and substituted with intravenous antibacterials with enhanced activity against *Pseudomonas aeruginosa* with the first onset of fever. The use of oral antibiotics among low-risk, neutropenic patients with fever is guided by the use of standardized scoring systems (e.g., MASCC index).[1]

Mucositis, with breakdown of oral and gastrointestinal mucosal barriers, is common during this period. This condition can predispose to sepsis from bacterial and fungal organisms that typically colonize the gastrointestinal tract. The most common serious infections occurring in neutropenic patients with mucositis are bacteremias due to viridans group streptococci and gram-negative bacilli. Such infections are particularly common during the first several weeks following HSCT, so broad-spectrum antimicrobial prophylaxis is generally given during this time period. The propensity of viridans streptococci to develop resistance to quinolones and gram-negative bacilli to be resistant to quinolones and β-lactams means that there is no perfect preventive regimen.

Central venous catheter placement through the skin can lead to blood infection from colonizing gram-positive skin organisms, despite sterile, operative placement of these catheters and antisepsis cleansing procedures.[18] Because the gram-positive bacteremias, including those caused by coagulase-negative *Staphylococcus* species, usually are not immediately life threatening, direct prophylactic coverage often is not immediately provided. During workup of a new fever, some treatment guidelines advocate the administration of vancomycin for several days until blood cultures demonstrate no gram-positive bacteremia. The use of antimicrobial-coated bloodstream catheters can be effective in reducing rates of catheter-related bloodstream infections.

Once a gram-positive bacterial infection is identified, vancomycin therapy is often used empirically until the susceptibility profile is available and targeted therapy can be provided. There are concerns about the efficacy of vancomycin in treating serious *S. aureus* infections because of relative or frank vancomycin resistance. Similarly, if the patient is known to be colonized with vancomycin-resistant enterococcus and the Gram stain indicates gram-positive organisms in chains, therapy for empiric vancomycin-resistant enterococcus is appropriate until the bacterial identification and susceptibility profile is available, usually with daptomycin or linezolid.

Once a gram-negative infection is identified, empiric therapy that includes *Pseudomonas* coverage is continued until the susceptibility profile is available. In the severely neutropenic host, serious gram-negative infections are often treated with combination therapy consisting of a β-lactam plus either an aminoglycoside or a quinolone depending on the antimicrobial sensitivity pattern and patient comorbidities.[15] However, data demonstrating the superiority of combination therapy over β-lactam monotherapy are lacking. The emergence of extended-spectrum β-lactamase producing gram-negative bacilli is a particular concern in patients with significant antimicrobial exposure as are the development of infections with pan-resistant organisms, such as multidrug-resistant *Acinetobacter baumannii* (see box on Treatment of Drug-Resistant Gram-Negative Bacilli). For many infections, the regimen then can be tailored to a single agent and continued for 2 weeks after the last positive culture in clinically responding patients. Therapy with a carbapenem resistant to β-lactamase hydrolysis is required if an organism is isolated that is known to have an inducible β-lactamase enzyme (e.g., *Enterobacter*).

For bloodstream infections, repeat blood cultures should be drawn after 2 to 3 days of effective therapy to ensure that sterilization of the bloodstream has been achieved. Persistently positive blood cultures suggest the development of a deep-seated or endovascular site of infection such as infective endocarditis or suppurative thrombophlebitis. When a bloodstream catheter is proven to be the source of the infection,[12,18] removal of the catheter may be required for most, but not all, infections. At the end of a 14-day treatment course beyond the last positive culture, the patient should be transitioned to an oral gram-negative prophylaxis regimen if still neutropenic.

Antimicrobial agents with anaerobic activity should be added for neutropenic enterocolitis, enlargement of neck soft tissues during mucositis (Ludwig angina variant), or culture-documented anaerobic

Treatment of Drug-Resistant Gram-Negative Bacilli

The widespread use of antibiotic prophylaxis among immunocompromised patients has been associated with the development of antimicrobial drug-resistance, which is especially problematic among gram-negative bacilli. Drug-resistant organisms can colonize the GI tract for prolonged periods of time and emerge to cause serious infections during periods of neutropenia or other medical stress (e.g., following admission to the intensive care unit).

- *Pseudomonas aeruginosa* is the paradigm for drug resistance among gram-negative bacilli and often rapidly develops pan-resistance to antimicrobials. Serious pseudomonal infections are generally treated with two antimicrobial agents, although convincing data supporting this approach are lacking.
- Extended-spectrum β-lactamase (ESBL) production among *Enterobacteriacae* such as *Escherichia coli* and *Klebsiella pneumoniae* renders these organisms resistant to non-carbapenem β-lactam antibiotics. Treatment is generally with a carbapenem (e.g., meropenem), although a quinolone can sometimes be used.
- The presence of a *Klebsiella pneumoniae* carbapenemase (KPC) can occur among species other than *K. pneumoniae* and creates resistance to all β-lactam antibiotics including carbapenems. Resistance to quinolones is also typical, so therapy is limited to the polymyxins (e.g., colistin), or to tigecycline and the aminoglycosides depending on the organism's antibiotic susceptibility pattern.
- Like *P. aeruginosa*, *A. baumannii* can develop resistance to all known antimicrobials via a variety of mechanisms. This generally occurs among critically ill patients following prolonged stays in the intensive care unit. Treatment options may include polymyxins and sulbactam, a β-lactamase inhibitor that possesses some activity against drug-resistant *Acinetobacter*.
- *Enterobacter, Serratia,* and *Citrobacter* species can elaborate an AmpC β-lactamase following initiation of β-lactam therapy, which can result in a relapsing infection following an initial response. Thus clinicians treating such infections with penicillins or cephalosporins should closely monitor patients for the emergence of resistance. If resistance does emerge, AmpC-producing organisms can be treated with a carbapenem.
- Patients with multidrug-resistant gram-negative infections should be cared for in such a manner as to minimize spread of these dangerous organisms to other patients. Compliance with infection control protocols is paramount.
- Knowledge of the local epidemiology and antibiogram are important for preemptive and empiric antibiotic choices, especially against gram-negative rods
- A carefully designed and executed antibiotic stewardship program could curtail unnecessary antibiotic use, thereby decreasing antibiotic selection pressure with a resulting decrease in bacterial resistance rates.

infection. Infrequently, tuberculous and nontuberculous mycobacteria are responsible for infections in the bloodstream, catheters, and pulmonary tree. Infections of central catheters or catheter tunnels caused by rapidly growing atypical mycobacterial infections require a high index of suspicion, as well as specific culture media.[19] Organism identification and drug sensitivities may take several weeks. Tuberculous disease can be empirically treated based on risk factors. For patients without risk factors for tuberculosis, recovery of acid-fast bacilli will prompt therapy for suspected nontuberculous mycobacteria, usually with clarithromycin and either a quinolone or ethambutol until specific susceptibility information is available. Tailored therapy is often continued for a minimum of 3 to 6 months.

Viruses

Neutropenia per se is not a major risk factor for developing viral infections but concomitant lymphopenia is common and does predispose to infections with a range of viruses.[20] Respiratory virus infections are seasonal, except for parainfluenza. A frequent pathogen with clinical significance is respiratory syncytial virus, although influenza, parainfluenza, adenovirus, enteroviruses, the herpesviruses (including HHV-6), human metapneumovirus, and rhinovirus also produce diffuse interstitial infiltrates and pneumonitis.[20] HHV-6 and human metapneumovirus are not recovered with the usual tests ordered at the time of bronchoscopy, so a high suspicion for infection is required to order specific polymerase chain reaction (PCR) testing. Documented infection with RSV prompts contact and droplet isolation precautions. Treatment components may include aerosolized ribavirin, IVIg, and in some cases, monoclonal antibody therapy. However, proof of efficacy of these treatments remains elusive, and the disease can cause significant morbidity and mortality.[21] With respiratory syncytial virus infections, aerosolized ribavirin treatment appears safe, and trends of decreasing viral loads have been reported. Secondary graft failure or diffuse alveolar hemorrhage associated with parainfluenza virus infection has been sporadically reported following transplantation.

Patients with lymphopenia are susceptible to a range of herpes virus family infections. Herpes simplex reactivation infections typically manifest as oral or genital ulcers although more widespread involvement can occur and are treated with low doses of acyclovir adjusted for renal function (e.g., 5 mg/kg IV every 8 hours) or oral valacyclovir (1 g bid). Reactivation of VZV can be severe in immunosuppressed persons and is treated with higher doses of acyclovir (e.g., 10 mg/kg IV every 8 hours or oral valacyclovir, 1 g three times a day). Use of acyclovir to prevent reactivation of HSV will also prevent VZV reactivation. Because many patients have not been exposed to acyclovir chronically (except for patients previously treated with recurrent courses of acyclovir for frequent outbreaks of genital herpes), there is little reason to expect resistance to acyclovir. However, HSV infections that appear or persist through acyclovir prophylaxis should be considered acyclovir resistant until viral sensitivity testing can be performed, and consideration should be given to initiating treatment with foscarnet or cidofovir.[22] Reports of acyclovir-resistant varicella are extremely rare. Foscarnet infusions affect calcium homeostasis, so monitoring of ionized calcium and phosphorus levels is required during clinical use of the drug. The major side effect of cidofovir is renal toxicity, which can be reduced to some degree with probenecid and hydration. Clinically significant CMV infection can occur during neutropenia, but the antigenemia test cannot be used for diagnosis or monitoring of response to therapy in this situation, so DNA PCR methods are preferred in that setting.

Human herpesvirus type 6 (HHV-6) is ubiquitous, and reactivation commonly occurs in patients with significant immunosuppression. However, clinically significant disease due to HHV-6 occurs in only a small percentage of patients who have HHV-6 detected in their blood.[23] HHV-6 infection can manifest as fever or pancytopenia. Other recognized clinical syndromes include pneumonitis and encephalitis. Infection is diagnosed by quantitative PCR, although the exact levels of virus that indicate clinically significant disease are not known. Detection of virus in the first 3 weeks following transplantation may be associated with early skin maculopapular rash and acute GVHD, but it can also present without overt clinical symptoms. Prospective large-scale studies are needed to determine the role of HHV-6 infection. HHV-6 has 60% DNA homology with CMV, and treatment of documented infection usually is initiated with induction doses of foscarnet or ganciclovir. Responses to antiviral therapy are not universal, and benefits of foscarnet versus ganciclovir have not been determined.

Cidofovir, when combined with aggressive supportive measures, is considered an adjunct in treatment of BK and adenovirus-associated hemorrhagic cystitis. Similarly, cidofovir can be used to treat disseminated adenovirus infections typically three times a week at 1 mg/kg/day, along with probenicid and hyperhydration.

Fungi

Most yeast infections in immunosuppressed patients are caused by *Candida*.[24] Candidal organisms that colonize the mouth and gut proliferate when antibacterial agents suppress the coexisting bacterial flora population. Guidelines for the treatment of candidiasis have been issued.[25] Patients who are clinically stable generally can be treated with fluconazole unless there has been previous azole exposure or mold infection is also a concern. Unstable patients or those who have been receiving an azole are usually treated with an echinocandin. Prevention of candidemia among allogeneic HSCT recipients is generally achieved with fluconazole. However, fluconazole does not have activity against some nonalbicans *Candida* species (e.g., *C. glabrata, C. krusei*) and all molds (e.g., *Aspergillus, Fusarium,* the Mucorales species). Among patients colonized with yeast species other than *C. albicans* and among heavily pretreated patients who may have incubating mold infection, prophylaxis using a mold-active triazole (e.g., posaconazole) or an echinocandin is preferred.[26]

Although less common than *Candida* infections, mold infections in immunocompromised hosts are a significant source of mortality, with aspergillosis being the most common (Fig. 88-5). Because such infections are difficult to diagnose using standard microbiologic techniques, there has been significant interest in developing more effective screening tests. When used regularly, the serum *Aspergillus* galactomannan ELISA may allow for earlier diagnosis of invasive aspergillosis in some patients.[27] The test is troubled by difficulties with both false-positive and false-negative results and thus needs to be interpreted as part of the overall clinical picture rather than as a standalone diagnostic tool. The development of a fungal infection in a patient receiving voriconazole should raise concern for mucormycosis, which is the second-most common mold infection in many transplant centers. Mucormycosis can rapidly disseminate through the lungs, sinuses, GI tract, and skin, which is uniformly fatal in patients with hematologic malignancies if not diagnosed early and aggressively treated.[28]

Although in vitro antifungal susceptibility testing for yeasts is not as well established as antibacterial testing, susceptibility from bloodstream or invasive isolates can be helpful in the management of infections, especially if the patient will require transition to longer-term oral therapy. Long-term treatment with newer azoles may be valuable in responding patients. Echinocandins cannot be used to treat *Cryptococcus* or Mucorales as monotherapy, but there may be a role for echinocandin in combination treatment for Mucorales. Mucorales species are generally susceptible to amphotericin B and posaconazole, although there are interspecies variations in susceptibility. In the case of mold infections, echinocandin agents may be fungistatic, rather than fungicidal, because interruption of fungal cell wall synthesis is limited to areas of hyphal branch points and growing hyphal tips. Because susceptibility testing for the echinocandin agents is of uncertain reliability, use of an echinocandin after the susceptibility profile has returned should be limited to nonneutropenic patients with uncomplicated candidemia. At present, the efficacy of combination drug therapy is unproven, but such therapy is often used in situations associated with high mortality. Clinical experience, but little clearly documented evidence, supports the value of extended combination antifungal therapy. Molds that often are resistant to amphotericin but may be susceptible to voriconazole or posaconazole include *Fusarium, Scedosporium* or *Pseudallescheria,* and *Trichosporon* (see box on Use of Antifungal Agents in Combination).

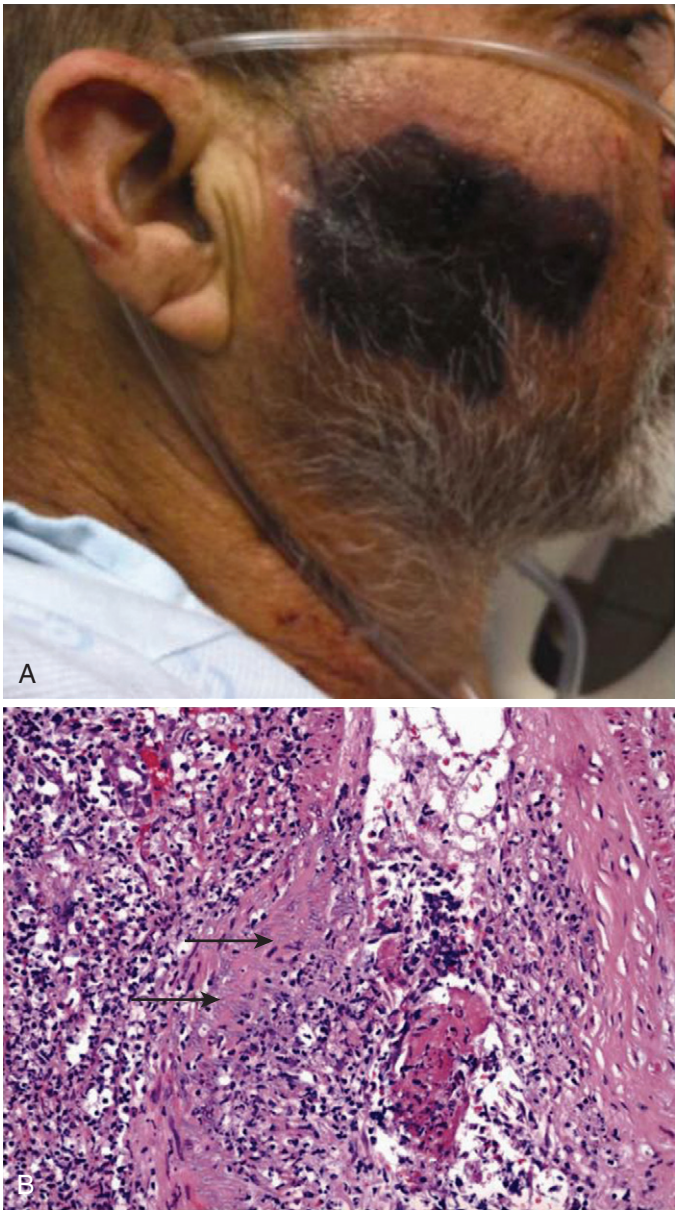

Figure 88-5 EXAMPLES OF ASPERGILLOSIS. **A,** Cutaneous aspergillosis in a patient with lymphoma treated with high-dose steroids. **B,** Invasive aspergillosis with organism invading into blood vessel wall *(black arrows).*

Malignancy-Associated Fever and Drug Fever

Although fever usually indicates the presence of infection, relapsing malignancy, autoimmune-granulomatous, collagen vascular diseases, or immunologic drug reactions can also be sources of fever in the immunocompromised host.[29] Malignancy or drug-associated fevers are the most common causes of persistent noninfectious fevers in cancer patients, but these are "diagnoses of exclusion" that require extensive clinical, radiographic, and microbiologic workup for occult infection until a noninfectious cause is considered most likely. All too often, patients receive escalating empiric broad-spectrum antibiotic therapy during this workup, which should be discouraged in clinically stable patients. Several clinical clues may favor a diagnosis of malignancy-associated fever, including (1) a prior history of fever at the time of initial malignancy diagnosis and (2) response of the fever to a trial of naproxen.[2] Patients with drug-associated fever often appear clinically well with relative bradycardia during periods of fever. Drug fevers typically develop 1 to 3 weeks after the start of a drug (β-lactams, sulfas, vancomycin, and phenytoin are among the most common inciting agents) and resolve, on average, within 48 hours of drug discontinuation unless the patient also has an accompanying rash. Drug-associated fever with rash and liver function test or complete blood count abnormalities (e.g., thrombocytopenia and eosinophilia) are often indicative of more severe reactions that should prompt immediate discontinuation or substitution of the likely offending medications.

Use of Antifungal Agents in Combination

The development of new antifungal drugs gives the clinician more options for prophylaxis and therapy than in previous years. There is an overall level of simplicity to the drug choices once their mechanisms of action are understood. The polyenes, including amphotericin products and the topical agent nystatin, attach onto ergosterol in the fungal cell membrane and are considered fungicidal, because cytoplasm leaks out, and individual cells die. The azoles, including fluconazole, itraconazole, voriconazole, and posaconazole, prevent the formation of new ergosterol. Azoles are considered fungistatic, because removal of the drug permits cell regrowth. Theoretically, use of an azole together with a polyene may have an overall static effect for an established infection as the ergosterol target for the fungicidal polyene is depleted. However, this combination may have advantages in terms of enhanced spectrum of activity. The echinocandins, including caspofungin, micafungin, and anidulafungin, prevent interaction of the catalytic and regulatory subunits of the β-glucan synthesis enzyme, so less β-glucan is formed for the cell wall. The scaffolding for the fungal cell wall is not maintained, and a dividing cell may burst open when trying to extend the new cell wall over daughter cells. The echinocandins are considered fungicidal for yeasts but fungistatic for molds, because drug activity is concentrated at only the tips of the extending hyphae with little effect on less metabolically active subapical compartments of the fungus. Combination therapy may have the most effect when a cell wall agent (an echinocandin) is used together with a cell membrane agent (a polyene or an azole). There is no role for three-drug therapy (an echinocandin, a polyene, and an azole). Aside from cases of cryptococcal meningitis, in which the importance of combination therapy is well established, the benefits of frontline use of combination antifungal for molds remain controversial, although active investigation continues in clinical trials. The value of combination regimens as salvage therapy for refractory mold infections remains uncertain.

INFECTION MANAGEMENT IN THE HEMATOPOIETIC STEM CELL TRANSPLANT RECIPIENT: A MODEL OF SEVERE IMMUNE DEFICIENCY

Infection is a major cause of morbidity and mortality in HSCT recipients. Such patients are susceptible to a wide range of infections, but the risk for a particular infection depends on a multitude of factors, including the type of transplantation, the length of time since transplantation, and the development of GVHD. A summary of common infections occurring in HSCT recipients is shown in Fig. 88-6.

Pretransplantation Prophylactic Techniques in Hematopoietic Stem Cell Transplant Recipients

Over the four decades during which HSCT has evolved, antimicrobial prophylaxis regimens have advanced to prevent common or high-risk infections.[3] This is balanced by problems associated with the preventive regimen, including toxicity, overgrowth of resistant organisms, and sometimes high cost. Algorithms for these preventive regimens evolve with changes in epidemiology, diagnostic methods, and new treatment agents for infections. Despite an overall preventive approach, infections still occur when a severe immune defect persists, when the infecting inoculum of organisms is large, when diagnostic methods are not sensitive enough for early detection, or when infecting agents overcome the effect of the antimicrobial agents. Measures taken to prevent infection in the preengraftment HSCT patient include pretransplantation serostatus blood workup, environmental measures to prevent infection (including frequent handwashing), and common sense.

Assessment of Pretransplantation Serostatus

Current pretransplant serologic testing of donor and recipient includes assaying for latent viruses (herpesvirus antibodies, hepatitis panels, and human T-cell lymphotropic virus antibodies [human

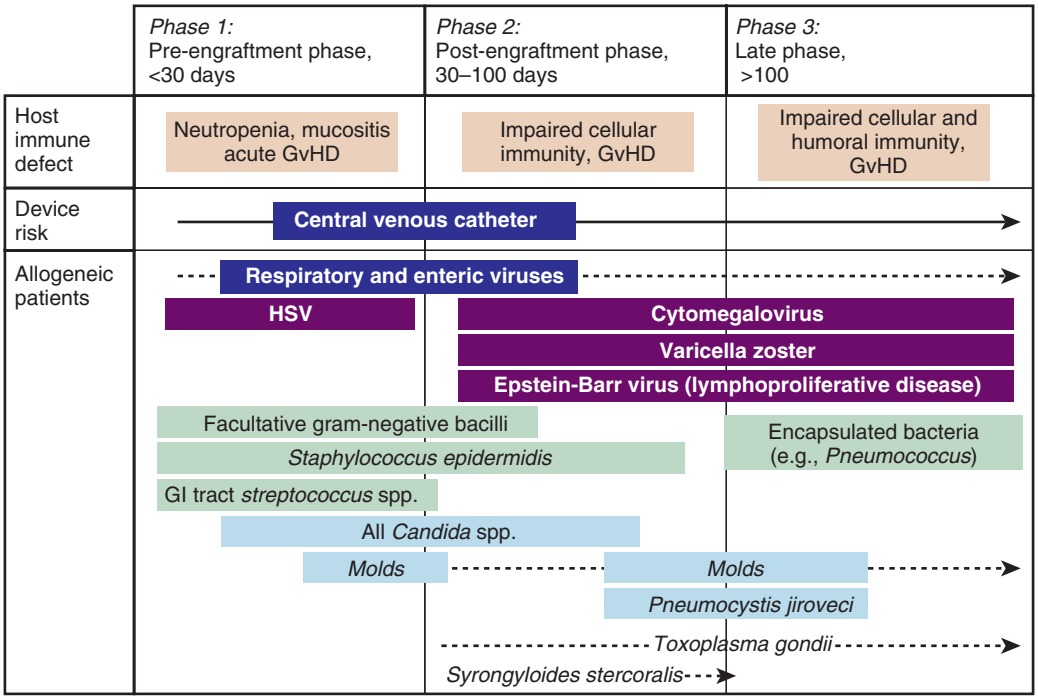

Figure 88-6 TIMING OF INFECTIONS FOLLOWING HEMATOPOIETIC STEM CELL TRANSPLANT. *GVHD,* Graft-versus-host disease.

T-lymphotropic virus I/II and HIV 1/2]) and syphilis. Antibody tests that are checked variably among individual transplantation centers include VZV, EBV, and *Toxoplasma*.

Herpes Simplex Virus

If the antibody test for HSV indicates prior infection or if the patient provides a clinical history of prior HSV infection (i.e., mucosal sores), latent infection exists and has the potential to reactivate during periods of T-cell suppression and neutropenia. This patient requires prophylactic medication (e.g., acyclovir or oral valacyclovir), which targets HSV for the neutropenic phase of transplantation. HSV lesions can appear as black scabs on the outside of the lips, white- to yellow-based ulcers when found on oral mucosa, or as an unusually severe exacerbation of mucositis or esophagitis. HSV prophylaxis administered until recovery from neutropenia may be helpful even in patients receiving nontransplantation chemotherapy such as acute leukemia induction therapy.

Cytomegalovirus

If the candidate is CMV seropositive before transplantation, the recipient should be followed with periodic (usually weekly) diagnostic monitoring tests (e.g., pp65 antigenemia or PCR) for 10 to 20 weeks. No special measures are needed during neutropenia because a detectable circulating white count usually is necessary for reactivation of CMV. If the patient is CMV seronegative before transplantation but the donor is seropositive, the same monitoring algorithm used for the CMV-seropositive patient is needed.

If the donor and recipient are CMV seronegative before transplantation, infection through blood products is possible; therefore exclusive use of CMV-seronegative blood products or other means of preventing CMV seroconversion, such as leukocyte depletion by filtration, are recommended. CMV monitoring should be followed weekly, but the duration of this testing can be shortened by 50%, to 6 to 10 weeks, because late infection in seronegative recipients is uncommon.

Varicella, Human Herpes Virus Type 6, and Epstein-Barr Virus

A history of chickenpox is an adequate surrogate for performing the VZV antibody test. As an alternative to ordering varicella serology on every patient, the test could be ordered in patients with no history of varicella infection or vaccination.

Acyclovir used to prevent reactivation of HSV during neutropenia will also prevent occurrence of clinical VZV infection in most transplantation recipients. Later after transplantation, when acyclovir prophylaxis may have been discontinued, VZV reactivations usually are recognized by their characteristic dermatomal distribution, and treated using acyclovir or valacyclovir.

Serology for HHV-6 is not tested before transplantation because more than 95% of adults are seropositive for the virus. The transplantation recipient receiving minimal herpesvirus antiviral therapy during the transplantation procedure is at risk for reactivation of HHV-6. Whether the CMV-seronegative or HSV-seronegative recipient with a CMV-seronegative donor who ordinarily would receive no antiviral prophylaxis is at highest risk is not known. Additionally, the consequences of asymptomatic and untreated HHV-6 reactivation are not known.

The vast majority of adult patients undergoing transplantation and their donors are EBV seropositive. EBV reactivation is in the differential diagnosis of any new mass, such as enlarged nodes or lung nodules after transplantation (Chapter 52). Now that sensitive quantitative EBV viral load tests and effective treatments, such as rituximab, are available, investigators are monitoring high-risk recipients with quantitative viral load studies.[30]

Hepatitis B and C

Hepatitis B (core antibody, surface antibody, and surface antigen) and hepatitis C serologies are tested in donor and recipient before transplantation. Hepatic dysfunction from either hepatitis B or C after HSCT can lead to life-threatening liver complications, including venoocclusive disease and acute hepatic necrosis. Short-term complications are usually due to hepatitis B, whereas the long-term complication of cirrhosis is due to hepatitis C. The risk for hepatitis in the recipient can be reduced by antiviral therapy for recipients and donors who have detectable viral loads and by transfer of immunity from donor to recipient. A hepatitis-infected individual can be used as a donor if no alternative donor is available or if the intended recipient already is seropositive.

The risk for transmission is small when the hepatitis B–seropositive donor has an undetectable viral load; however, careful follow-up of recipients is recommended. A surface antigen-positive hepatitis B donor with a high viral load should be treated with lamivudine or another agent to reduce the circulating viral load before transplantation. High-circulating hepatitis C viral load in the seropositive donor for a seronegative recipient is an indication for interferon or other antiviral therapy of the donor before HSCT.

If the potential recipient has serologic evidence of infection with hepatitis B or C before transplantation, viral load levels should be checked before and monitored after HSCT. High hepatitis B viral load ($>10^5$ copies/mL) is the most important risk factor for reactivation in patients positive for surface antigen undergoing HSCT. High-circulating hepatitis B viral load in the intended recipient is an indication for lamivudine. There is no evident correlation between hepatitis C genotype and type or severity of liver disease after transplantation. There is currently no effective therapy for hepatitis C in the HSCT recipient, although new agents are being developed.

Human Immunodeficiency Virus

A positive donor HIV test for a recipient candidate not known to be seropositive is a contraindication for donation. If the screening test for HIV is positive, a Western blot study should be completed to confirm the result because of the potential for false-positive testing.

Syphilis

If the indirect screening test for syphilis returns positive and is confirmed by a direct test, high-dose penicillin treatment should be given for 10 days after transplantation.

Toxoplasma

Historically, 15% of patients who undergo transplantation in the United States are seropositive for *Toxoplasma,* but this percentage may be higher for European centers. The risk for reactivation among seropositive patients is 2%, for an overall incidence of less than 1% of HSCT recipients. It is suspected that low-dose sulfa-based regimens, such as those used to prevent *Pneumocystis* pneumonia, may be effective in preventing *Toxoplasma*.

Review of Commonsense Measures to Prevent Infection

Commonsense measures that should be discussed before transplantation or aggressive nontransplantation chemotherapy include attention to diet, travel, crowds, and pets. Additionally, a history of family or social exposure to tuberculosis should be used to guide whether or not a Mantoux test is applied before therapy.

Diet should be reviewed for herbal supplements or restricted foods. Patients may not recognize that most supplements will have to be discontinued after HSCT. Ground meat products need to be thoroughly cooked so that bacteria, distributed onto meat in the grinding process, are killed. Any fruits or vegetables that cannot be peeled should be washed. Salad bars are associated with occasional transmission of infections. Food products or supplements that inherently contain infectious organisms should be avoided, including undercooked eggs. Blue cheeses have molds spiked into the cheese wheel as they are curing and should be avoided. Soft cheeses carry the potential risk for *Listeria* infection. Yogurt contains *Lactobacillus* that, rather than causing gut problems, has been found to cause infection in other sites, including the lungs after aspiration events.

There are no particular travel restrictions, but strategies to minimize transmission of infectious diseases have been summarized. Some social situations, such as sitting in a crowded movie theater or classroom, increase the risk for acquiring a viral illness. Turning away from individuals who are coughing or sneezing may be helpful in preventing the transmission of infections. Patients need instruction to remember to complete the cycle of infection prevention by washing their hands as soon as possible after being close to such an individual. Given outbreaks of noroviruses (Norwalk-like viruses) on cruise ships and other types of outbreaks (e.g., *Staphylococcus*) commonly associated with the close living quarters during this type of travel, cruise ships should be avoided.

Healthy dogs and cats are considered acceptable pets. However, the immunosuppressed patient should not be responsible for scooping cat litter because of potential *Toxoplasma* cyst exposure. Similarly, the patient should not play in sandboxes because these areas are concentrated sites that feral outdoor cats may use as litter boxes. Because reptiles of many sorts have been reported to be infected with *Salmonella,* patients should not touch these animals or the insides or outsides of their cages or tanks. The heated water of tropical fish tanks carry *Mycobacterium marinum*. *Cryptococcus* and *Chlamydophila* (formerly *Chlamydia) psittaci* can be transmitted from large pet birds.

Environmental Measures to Prevent Infection

Persons entering the patient's room to perform an examination or touch the patient (including visitors as well as health care workers) should wash their hands outside the room. Ideally, the institution will have handwashing sinks in the hallways outside patient rooms for this purpose. During respiratory virus season, the infection control department often adds extra signs to doorways and other places in the wards to remind visitors of the importance of handwashing. Staff and visitors without control of body secretions should not be permitted to have direct patient contact.

Some infectious situations require special isolation procedures. Contact isolation (gloves and gowns) is used for patients with adenovirus, methicillin-resistant *S. aureus,* or *Clostridium difficile* infection. Droplet precautions are added to contact precautions for respiratory virus or varicella infection. Carriers of vancomycin-resistant *Enterococcus* are placed in contact isolation until they meet defined criteria for discontinuation of isolation.

Laminar airflow is a cumbersome and expensive isolation technique that has been largely outmoded with advances in airflow and isolation technology as well as current antimicrobial therapy. Historically, it has been most commonly used for patients with aplastic anemia or those receiving T cell–depleted transplants.

High-efficiency particulate air (HEPA) filtration has replaced laminar airflow as the means for preventing infection through ventilation. With at least 12 air exchanges per hour, HEPA filters are capable of removing particles greater than 0.2 μm in diameter, such as mold spores. Patients often ask whether they should purchase portable HEPA filters for the home or apartment they will occupy after hospitalization. In the broadest sense, this is an extra measure that can be used on an individual basis. If portable HEPA filters are used, they should be obtained for each room that the patient will occupy during the day and night, and each unit should be sized for the individual room. A beneficial effect of HEPA filtration in the outpatient setting has not been demonstrated.

Infection in the Hematopoietic Stem Cell Transplant Recipient Preengraftment

The major risk factors for infection in the preengraftment period include drug-induced mucositis, profound neutropenia, and the presence of indwelling catheters. Thus the major infections observed in this period are due to bacteria that colonize the skin and GI tract (e.g., viridans group streptococci and gram-negative bacilli), *Candida,* and respiratory viruses, especially in the winter months (see Fig. 88-6). Reactivation of latent or partially treated fungal infections can also occur, with *Aspergillus* being well recognized. The propensity of patients to develop such infections has led to widespread use of prophylaxis with an antiviral, antibacterial, and antifungal agent during this time period.

Infection in the Hematopoietic Stem Cell Transplant Recipient After Engraftment

Once engraftment has occurred, the major risk factors for infection include immunosuppression used to treat GVHD and mechanical disruption of mucosal barriers, particular indwelling venous catheters. Viral infections that reactivate after engraftment often are related to defective T cell–mediated immunity and include CMV, adenovirus, and hepatitis viruses. Outpatient HSCT recipients inhale mold spores and *Pneumocystis* cysts from the environment, so common exogenously acquired infections include aspergillosis, mucormycosis, and *P. jiroveci* (previously *carinii*). Bacterial infections associated with defective cell-mediated immunity such as pneumococcosis, nocardiosis, and atypical mycobacterial disease can also occur in association with significant immunosuppression (Fig. 88-6).

Cytomegalovirus

CMV causes significant morbidity and mortality in transplant patients both directly and because of its immunosuppressive effects that predispose patients to concomitant or sequential infection with bacterial and fungal pathogens. Use of prophylactic ganciclovir at engraftment usually is avoided because it leads to myelosuppression and possibly a higher incidence of late CMV disease. Instead, the patient is treated with ganciclovir when weekly PCR or pp65 antigenemia monitoring test meets a positive threshold. Initial viral load levels do not predict disease. CMV infections are treated with an induction ganciclovir regimen followed by approximately 6 weeks of a maintenance regimen (half the induction dose). The duration of induction (1 to 3 weeks) varies by institution, but in general 1 week is used for low-grade infection, 2 weeks for high-grade infection, and 3 weeks for end-organ disease. A rising viral load, when checked weekly during the first month of preemptive therapy, signals the need for continued induction dosing or repeat induction dosing.

When the end-organ manifestation of CMV is pneumonitis (recovery of CMV from a deep lung specimen along with an interstitial infiltrate on chest radiograph), IVIg is added on an every-other-day basis for the duration of induction. When CMV manifests in an end organ other than the lungs, use of IVIg is not as clearly useful. Some centers add IVIg when the patient's total IgG level falls below 400 mg/dL. Dosing schedules vary from IVIg given once weekly for 3 weeks to every other day for the duration of induction, similar to therapy for pneumonitis. Ganciclovir resistance is uncommon, but when it occurs, foscarnet or cidofovir may be used.

Varicella-Zoster Virus

Varicella-zoster virus reactivations from latency (zoster) usually are recognized by their characteristic dermatomal distribution. No temporal pattern is seen, viremia can occur concurrently, and multiple episodes are possible but uncommon. For patients who have been treated for a zoster episode after HSCT, some centers provide acyclovir prophylaxis until 1 year after HSCT. Less common VZV clinical manifestations that can result in severe infection and may require molecular testing or viral culture for diagnosis include hemorrhagic pneumonia, hepatitis, central nervous system disease, thrombocytopenia, and retinal necrosis.

HSCT recipients with a negative or unknown VZV disease history and a significant exposure to active varicella are susceptible to primary VZV infection. For these patients, varicella-zoster immune globulin should be provided within 96 hours of exposure. Patients with positive serology can become clinically reinfected after exposure and should be provided with acyclovir prophylaxis; however, such patients do not require varicella-zoster immune globulin.

Epstein-Barr Virus

EBV causes a spectrum of scenarios after stem cell transplantation, ranging from asymptomatic but detectable viremia, hemophagocytic syndrome, or posttransplant lymphoproliferative disorder (Chapter 52). The incidence of EBV-related complications is higher in mismatched donors, patients with T cell–depleted transplants, and patients receiving intensive immunosuppression (e.g., antithymocyte globulin). Posttransplant lymphoproliferative disorder after allogeneic stem cell transplantation most often is of donor origin. Quantitative EBV viral load diagnostic testing is relatively new and not standardized, so the algorithms for monitoring and initiation of treatment vary. Recognition of greater than 1000 viral copies/mL of blood requires investigation, repeated testing, and possibly treatment, especially in high-risk patients. Direct antiviral agents have limited impact on reducing detectable EBV viral loads. General treatment approaches involve reduction of immunosuppression and rituximab or donor lymphocyte infusion (see Chapter 52).

Invasive Mold Infections

Invasive fungal infections are among the most feared complications of HSCT both because of their high mortality rates and the difficulty in establishing a diagnosis.[4] Among HSCT recipients studied at autopsy, yeast and mold infections were common, seen in more than 25% of deaths. The probability of survival is higher in recent years, likely due to newer and more effective agents, as well as nonmyeloablative conditioning. Posaconazole has been shown to be effective in preventing invasive fungal infections during GVHD, but erratic absorption and the lack of an intravenous formulation limit its efficacy.[5] Mold spores may initiate a localized infection in the lungs or sinuses that, after intensive immunosuppression for GVHD, may disseminate to the skin, abdominal organs, or central nervous system. Treatment of central nervous system infections should include voriconazole, which attains cerebrospinal fluid levels approximately 50% those of plasma or central nervous system tissue levels approximately 200% those of plasma. Infection with Mucorales organisms tends to have later onset than infection with *Aspergillus* (after day 90).[4]

Pneumocystis

The most common presenting symptoms of *Pneumocystis* infection are dyspnea, cough, and fever. Diagnosis requires demonstration of the organism in silver-stained specimens (bronchoalveolar lavage or lung biopsy). Disease occurs by both new infection and activation of latent infection. Most patients present between day 40 and day 80 after HSCT, but cases as early as day 12 and as late as 42 months after HSCT have been reported. Once lymphocyte function is more reconstituted, *Pneumocystis* infections are rare. Prophylaxis options include trimethoprim-sulfamethoxazole, aerosol or intravenous pentamidine, dapsone, and atovaquone. Among patients treated with dapsone after transplantation, increased red blood cell and platelet transfusion requirements are noted. Prophylaxis is generally discontinued 1 to 2 years after HSCT, or later if immunosuppression is ongoing.

Parasitic Infections

Toxoplasma gondii is a ubiquitous pathogen that causes significant morbidity and mortality. Although relatively uncommon, toxoplasmosis is recognized as a cause of cerebral, ocular, and lung disease in immunocompromised patients. Accurate diagnosis of this treatable infection is critical. PCR-based testing has become an adjunct method for diagnosis, occasionally replacing tissue biopsy.

Infection Issues in the Late Posttransplantation Period

Encapsulated Organism Prophylaxis

Penicillin prophylaxis has decreased the incidence of infection-related morbidity and mortality from polysaccharide-encapsulated bacteria (*S. pneumoniae, H. influenzae* type b, *Neisseria meningitidis*). Penicillin-resistant pneumococcal infection has been reported, prompting consideration of alternate prophylaxis, such as a change from penicillins to quinolones. Prophylaxis is generally discontinued 2 years after HSCT, or later if GVHD and immunosuppression are ongoing at the 2-year time point. Once the patient is ready for vaccinations, conjugate pneumococcal, meningococcal, and *H. influenzae* type b vaccines are given.

Vaccination

Recipients of HSCT frequently lose antibody responses to viral and bacterial pathogens previously targeted by childhood vaccination. Although practice varies among transplantation centers, killed-virus vaccines are often given at 1 year after HSCT and live-virus vaccines approximately 2 years after HSCT for patients without GVHD.[6] For adults, Tdap (formulation of reduced-antigen, combined diphtheria-tetanus-acellular pertussis vaccine) has replaced Td (diphtheria-tetanus booster vaccine) as a means for decreasing the adult reservoir of pertussis. For protection against hepatitis, the combined vaccine providing protection against both hepatitis A and B can be used. The efficacy of vaccination is influenced by the time elapsed since transplantation, the nature of the hematopoietic graft, the presence of GVHD, and the use of serial immunization. Guidelines have been published (Chapter 110, Table 110-4).

CHAPTER 89

INDWELLING ACCESS DEVICES

Franklin W. Huang and Janet L. Abrahm

Indwelling devices that provide prolonged access to the venous and central nervous systems have permitted novel and more comfortable forms of treatment for children and adults. Indwelling central venous access devices are essential for patients who require frequent withdrawal of blood specimens or administration of blood or blood products, peripheral stem cell apheresis, parenteral nutrition, or infusional therapy with medications such as chemotherapeutic agents, antibiotics, or pain medications. These devices facilitate therapies in the outpatient and home settings. Similarly, through the use of indwelling epidural or intrathecal catheters and Ommaya reservoirs, prolonged access to the cerebrospinal fluid (CSF) may be obtained for the delivery of chemotherapy, antibiotics, antifungal agents, or pain medications. The choice of the appropriate device and application of careful maintenance procedures can minimize the associated complications and maximize the patient's quality of life. As therapies continue to become more intensive, maintenance of adequate, reliable venous access is a critical issue for the management of many patients with hematologic diseases. Since 1973, when the Broviac catheter was first introduced, the sizes and uses of indwelling central venous access devices (CVADs) have expanded dramatically. Although exact numbers are not known, it has been previously estimated that 5 million CVADs are placed in patients in the United States every year.[1] We currently estimate that 5 to 10 million CVADs are placed in patients in the United States every year.

INDWELLING CENTRAL VENOUS ACCESS DEVICES

Chronic venous access devices can minimize the physical and psychologic discomforts of repeated venipuncture; prevent venous thrombosis, phlebitis, and vesicant infiltration; maintain patient mobility; and minimize hospital stays. Certain patients with hematologic diseases are at increased risk for the development of thrombophlebitis from standard (peripheral) intravenous lines and may therefore be best served by an indwelling access device. Factors associated with this increased risk include age of the patient (60 years or older); certain characteristics of the solutions being infused (e.g., hypertonicity of the solution, irritating diluents such as alcohol, highly acidic or alkaline pH, particulate matter in the solution); type of drugs infused (vesicant chemotherapy, certain antibiotics, dexamethasone, furosemide, phenytoin); factors associated with the catheter itself and its insertion (size and composition, traumatic insertion, microbial contamination); and duration of infusion (85% of cases of phlebitis occur 24 to 48 hours after placement of the intravenous line). Because patients with these risk factors or with visibly poor peripheral venous access can usually be identified before therapy begins, early placement of an indwelling device is reasonable. To minimize the occurrence of septic episodes, the devices should be placed before the administration of agents that induce neutropenia. With platelet transfusions, catheters and ports can be safely placed surgically or radiologically in patients whose thrombocytopenia (platelet count less than 50,000/mm^3) is caused by conditions other than disseminated intravascular coagulation.

DEVICE TYPES

Catheters

In all indwelling catheters used for prolonged central venous access, the proximal capped portion of the catheter exits from a subcutaneous tunnel on the chest or abdominal wall while the distal tip is indwelling in a central vein (Fig. 89-1). All catheters are composed of radiopaque elastomeric hydrogel, polyurethane, or silicone elastomer but differ in types of opening and internal diameter. Catheter design varies among manufacturers with some catheters having end openings at the distal tip, others having side openings, and some having end and side openings.

Catheters with a simple opening at the distal tip include those placed at the bedside (i.e., midline catheters and peripherally inserted central catheters [PICC]) and the tunneled Hickman, Broviac, and apheresis catheters, which are surgically inserted. Hickman catheters can have single, double, or triple lumens and have an anchoring cuff in subcutaneous tissue. Broviac catheters have a smaller internal lumen diameter than Hickman catheters and are primarily used in the pediatric setting. Midline catheters, which do not extend into the veins beyond the arm itself, come with single or double lumens. Their use is restricted to nonirritating and nearly isoosmotic therapies and has declined in favor of the more versatile PICCs. PICCs terminate in the superior vena cava (SVC) and are available as single, double, or triple lumen catheters. The tunneled catheters are generally double or triple lumen and extend to the SVC. For apheresis (e.g., for peripheral stem cell harvest), for preoperative exchange transfusions, or for vasoocclusive crisis in patients with sickle cell disease, the catheters used are shorter, with larger lumens, than Hickman catheters to allow for flow of large volumes.

Valved catheters (e.g., Groshong, PASV) are available in a variety of internal diameters and are designed to prevent the reflux of blood into the catheter tip. The valve allows the catheter to be flushed with saline solution rather than with heparin. The PASV has a pressure-sensitive valve at the proximal end, and the Groshong three-position slit valve is adjacent to a closed distal tip. The valve remains closed at rest but opens outward for infusion when positive pressure is applied and opens inward for aspiration when negative pressure is applied. Valved catheters are also available as peripherally inserted devices.

For patients requiring multiple simultaneous therapies (e.g., nutritional support or infusional therapy, along with blood sampling and blood product administration), all the previously mentioned catheters are available with double lumens, and a triple-lumen tunneled catheter is available as well.

Implantable Central Venous Devices (Ports)

In the United States, more than 200,000 ports are implanted annually, and their use is increasing. Ports provide potentially lower infection rates than tunneled central venous catheters (CVCs) and are

useful for long-term intermittent access that is needed in outpatient chemotherapy. These totally implantable CVADs consist of single- or dual-lumen ports that may be round, square, oval, or hexagonal and are connected to a radiopaque silicone elastomer or polyurethane catheter (Fig. 89-2). Ports are also available in low profile (less depth) designs. The port includes a self-sealing silicone septum with a body of plastic or metal, both of which can cause an artifact on magnetic resonance imaging (MRI). The artifact effect is greater with stainless steel than with plastic. Many ports now available are MRI compatible. No portion exits onto the chest wall. The port is surgically placed in a subcutaneous pocket, and the catheter is inserted into a central vein. The single or double port is connected to a standard or valved catheter. Ports are available as one- or two-piece systems. The position of the distal tip of the two-piece system is more easily adjusted during insertion because it can be shortened at the port pocket before connection to the reservoir. However, with the two-piece system there is the potential for disconnection of the port from the catheter with resultant infiltration into the port pocket.

The Vortex port is designed with a tangential rather than perpendicular outlet tube to promote more efficient and thorough flushing of the port chamber. This design appears to inhibit buildup of thrombus or drug residuals in the port chamber, resulting in fewer complications than those associated with traditional ports.

Ports that can be placed in the antecubital fossa are also available but less frequently used. The peripherally implanted ports are smaller and flatter than is the standard port. Other implantable devices have self-contained pumps.

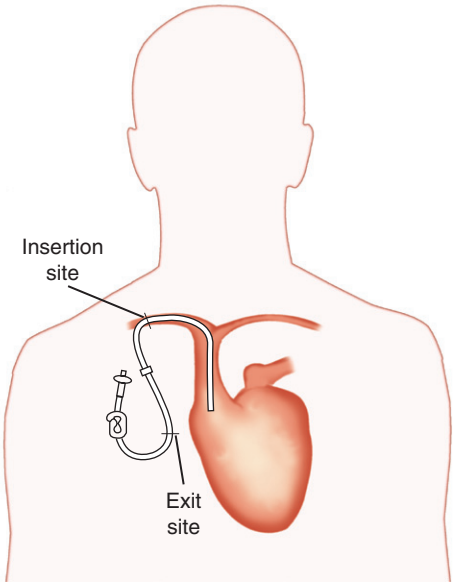

Figure 89-1 Schematic diagram of an indwelling central venous catheter in place. *Insertion site* refers to the insertion of the proximal end of the catheter into the chest wall. Clamp attached to the catheter is shown next to the Luer-Lok cap at the distal end. *(Modified from* Hickman Subcutaneous Port, Use, and Maintenance and How to Care for Your Hickman or Broviac Catheter. *Cranston, RI, Davol Inc.)*

DEVICE CHOICE

Patient characteristics and preference, as well as the duration of use, purposes for which the device is required, and relative complication rates all aid in deciding among the types of catheters and in choosing between catheters and ports (Table 89-1).

Patient Characteristics and Preference

The peripheral devices are helpful in patients with chest wall abnormalities that preclude the use of centrally placed catheters or ports (e.g., subcutaneous carcinoma of the chest wall, open wounds, tracheostomies, or fibrosis induced by radiation therapy).

In patients with a known heparin allergy or who develop heparin-induced thrombocytopenia (HIT), valved catheters that do not require heparin for maintenance are particularly appropriate for patients in whom continuation of a CVAD is necessary. Although

Table 89-1 Choices of Indwelling Venous Access Devices

	Duration of Use	Access in Thrombocytopenia?	Uses	Comments
Peripheral port	<3 mo	Yes	Patients with chest wall problems; intermittent access	Not commonly used
Tunneled CVC	>6 mo	Yes	Commonly used in leukemia induction chemotherapy and bone marrow transplant; used for hyperalimentation	Lower risk for infection than with nontunneled CVCs
PICC (peripherally inserted central catheter)	<6 mo	Yes	Can be accessed frequently; rapid infusion, vesicant infusion, hyperalimentation; useful in patients with limited peripheral access	Lower risk for infection than with nontunneled CVCs; can be placed and removed easily at bedside; can be placed in patients with thrombocytopenia (<50,000 plts per microliter) or with elevated INR
Port	>6 mo	No	Prolonged and intermittent access for chemotherapy administration and blood draws	Less infection risk than with catheters; placement and removal by surgery or interventional radiology; can be used for patient with sickle cell disease or hemophilia

rare, HIT from catheter flushes alone has been documented with heparin flush doses as low as 60 units per day. Valved catheters require somewhat less care than standard catheters and may be preferred for patients unable to care for a Hickman or Broviac catheter at home.

Children and adolescents have lower risks for complications with ports than with catheters; indeed, studies have indicated a significantly lower complication rate, especially in the youngest children, when ports are used rather than catheters. Implantable devices have several advantages for children in particular: they are cosmetically acceptable, cause less limitation of activities, are at less risk for accidental dislodgment or damage, and require less care when not in active use. Ports also have a lower rate of infectious complications in adult patients and are especially useful for adults who are unable to care for a catheter or who do not wish to do so, as well as for those who prefer a less visible access device.

Port systems are less successful in patients with hematologic malignancies because these patients are at an increased risk for developing any type of complication such as infection and thrombosis. Ports are also less successful when placed outside the cervical or infraclavicular areas because of factors such as tendencies for groin infections or catheter thrombosis in low-flow vessels. In patients receiving anti-VEGF therapy with bevacizumab, wound healing issues have been reported after port placement and have led investigators to suggest a 2-week period following port placement before initiating bevacizumab therapy.[2,3]

In obese patients and in patients with thrombocytopenia, the subcutaneous location of ports poses a problem. In the obese patient, it may be difficult to access a port placed deep in the antecubital fossa or chest wall. Needle stability may also be an issue for obese patients. If the needle length is not sufficient, it may be displaced or lifted out of the port by shifting flesh (i.e., if the patient lies on the affected side). For the patients with chronic thrombocytopenia (platelet count below 20,000/mm^3), the risk for hematoma associated with recurrent needle punctures required for access makes ports more problematic.

For hemophiliac patients, consensus recommendations for CVADs have been published to help guide clinicians in patient selection. Ports are recommended both for patients with and without inhibitors, in part to minimize infectious risks. CVADs can be advantageous for small children requiring frequent factor infusions, for facilitating home-based treatment and/or prophylaxis, for rapid and reliable response to a spontaneous bleed, or for administration of immune tolerance therapy.[4,5]

For sickle cell patients requiring chronic apheresis red cell exchange, the limited reported experiences have been poor with permanent access devices such as Vortex ports and double/dual ports. Furthermore, ports cannot accommodate the flow rates required by apheresis machines.

Duration of Use

In patients needing only short-term access (usually several weeks to months), PICCs are ideal. The average PICC is in place for 2 to 10 weeks, but some devices have functioned for more than 300 days. In patients needing a longer duration of infusion and more extensive supportive care, surgically placed catheters and ports are generally preferred. Catheters and ports have remained in place safely for months to years. Most ports remain in place until the patient dies. Of 707 ports studied in an oncology population, 72.4% were still in place at the patient's death (2 to 1960 days in use), and only 13.5% of the ports were removed at the end of therapy.

For patients who require continuous daily access such as during stem cell transplantation, tunneled catheters are preferred.

Purpose for Which the Device Is Required

PICCs are used for antifungal/antibacterial therapy, hyperalimentation, or infusion of chemotherapy regimens that may include vesicant agents. Their smaller bore makes them less useful for blood drawing or transfusion. Contraindications to PICCs include ipsilateral local cellulitis, thrombophlebitis, conditions that affect venous return (e.g., lymphedema, previous axillary node dissection, or hypercoagulopathy). Central ports are often considered for outpatient chemotherapy regimens lasting months and reduce the need for venipuncture for routine blood draws and repeated peripheral intravenous catheters.

In general, surgically implanted catheters are more useful than ports or PICCs in patients in whom frequent access to the device or frequent blood drawing or blood product administration is needed. The larger-bore catheters are more useful for blood drawing and blood product administration, because the incidence of clotting after such use is lower with them than with smaller-bore devices. If a port or a PICC is chosen, the catheter with the largest bore is recommended. In the larger-gauge PICCs, which collapse easily, blood drawing is usually more successful if a syringe is used instead of a vacuum tube collection system.

Continuous vesicant infusion may be more safely accomplished with catheters, because they avoid the danger of needle dislodgment and disconnection of the catheter from the septum associated with the implanted ports.

For support during autologous or allogeneic bone marrow transplantation, double- or triple-lumen catheters are the standard of care. In transplantation patients undergoing peripheral stem cell apheresis, silicone apheresis or the largest-bore standard catheters is preferred, because the internal diameter of the smaller catheters may not support the apheresis procedure. The complication rates for the large-bore

catheters in transplantation recipients are similar to those of other central venous catheters used for pheresis or transplantation, or both.

RELATIVE COMPLICATION RATES

PICCs cause more phlebitis than tunneled catheters, and earlier reports indicated that the infection rates associated with their use were also higher than those for tunneled catheters. A large analysis of various types of devices shows that PICCs have higher infection rates when used in inpatients as compared with outpatients, and ports appear to have the lowest infection rates overall.[6]

Conflicting data have been reported regarding the relative complication rates seen with tunneled catheters and ports, although the overall complication rate is probably lower for ports than for catheters. Many studies have found significantly higher rates of complications with tunneled catheters than with ports. The only complication that is no more likely with catheters than with ports is catheter occlusion. Patients with ports also reported fewer restrictions in activity and hygiene.

In HIV-infected patients, retrospective studies demonstrate that catheters appear to cause more infectious complications than ports. Hemophiliacs have higher infection rates than the oncology population for external and implanted venous access devices (71% versus 41%). Hemophilia patients with fully implanted CVADs were 31% as likely to develop an infection as those with external devices.[4] The presence of inhibitors seems to increase the infection rate, though the incidence of infection in inhibitor patients with ports was still only 33% of that with external catheters. There has been debate over potential bleeding risks into a port pocket, with associated infectious risk, versus ample risk reduction with newer recombinant hemostatic regimens such as activated prothrombin complex concentrate or rFVIIa. Given these considerations, this metaanalysis supported the use of fully implantable ports for hemophiliacs with inhibitors.

Sickle cell patients may also have higher complication rates of sepsis and thrombosis than the oncology patient. This may be due to the hypercoagulable state and frequent admissions with resultant antibiotic resistant colonization.

In children with cancer, risk factors for CVC-related complications included having a hematologic malignancy and being younger than 6 years of age at time of insertion. Single-lumen Hickman/Broviac catheters had fewer complications and greatest catheter survival, compared with double-lumen catheters or a PASV catheter.

For more details, see box on Choice of Device.

Choice of Device

We recommend indwelling venous access devices based on patient characteristics and preference, anticipated duration of use, purpose(s) for which the device is required, and relative complication rates among catheters and ports.

PICCs can be selected when duration of use will be 3 months or less. They are an appropriate choice when patients have chest wall problems, require outpatient-based treatments, and/or have thrombocytopenia. PICCs allow for vesicant infusions, antifungal and antibiotic therapies, and hyperalimentation.

Peripheral ports may be used longer than PICCs, but not longer than 6 months, and they may be chosen for patients with chest wall problems receiving outpatient-based treatments.

Tunneled catheters may be chosen for patients with thrombocytopenia who require frequent access, rapid infusion, or administration of vesicants. Valved catheters that do not require heparin are useful for patients who should not receive heparin. Like peripheral ports, they may be used for up to 6 months.

Of the various devices, central ports allow for the longest duration of use (more than 6 months). They are appropriate for outpatients, particularly children or adolescents, but they may be problematic in patients who are obese, especially if they are thrombocytopenic. They are used for rapid infusions and administration of vesicants and, if they have more than one lumen, for hyperalimentation.

DEVICE INSERTION

Catheters

Catheters can be inserted surgically or nonsurgically. In the hospital, appropriately trained physicians, nurses, or physician assistants generally place midline catheters and PICCs nonsurgically. Insertion failure can occur in 8% to 22% of attempts, although the failure rate decreases with experience. After careful skin preparation using a sterile technique (and for large-gauge introducers, local anesthesia) and under ultrasound guidance, the catheter is inserted 1 to 2 inches above or below the antecubital fossa into the basilic, cephalic, or median cubital vein. PICC catheters are advanced into the superior vena cava (or, less frequently, the axillary, innominate, or subclavian vein) and secured by sutures or sterile tape. Placement above the antecubital fossa is more acceptable to patients and interferes less with patients' activities of daily living. Radiologic confirmation of tip placement should be obtained before initiating therapy.

Tunneled Hickman, Broviac, and valved catheters (and ports) are inserted surgically in an operating suite or minor procedure room, physician's office, radiology suite, or at the bedside. All catheter insertion techniques include creating a subcutaneous tunnel on the anterior chest wall, pulling the catheter up through the tunnel, and positioning the catheter cuff in it, leaving its remaining proximal portion with the Luer-Lok tip exiting from the tunnel on the chest wall (see Fig. 89-1). The distal catheter tip is then usually placed percutaneously or by a cutdown technique into the central circulation through the axillary, subclavian, internal jugular, or cephalic vein and threaded into the superior vena cava under fluoroscopic guidance. Cutdown technique greatly diminishes the possibility of pneumothorax or hemothorax because the vessel is cannulated under direct visualization. Literature from the dialysis population and a retrospective study of oncology patients suggest that there is a lower incidence of symptomatic venous thrombosis when the catheter is inserted through the internal jugular vein.

The catheter position in the superior vena cava at the right atrial junction should be confirmed by chest radiography. In patients expected to need crutches for a prolonged period, catheters should be inserted through the internal or external jugular vein or in the subclavian vein lateral to the midclavicular line to prevent pinching the catheter in the costoclavicular space, which leads to catheter pinch-off and fracture.

No significant differences have been found in time to failure or in infection or obstruction rate of catheters inserted percutaneously ("blind" or landmark technique) rather than under direct visualization. Real-time ultrasound-guided insertion techniques are associated with fewer placement failures and complications compared with landmark techniques. One study of 589 blind placements had a 92% success rate, with 2.9% of catheters requiring repositioning. Especially thin or obese patients are identified as having a higher risk for insertion failure and complications when the landmark technique is used. Other patients at higher risk are those who have had previous major surgery or previous central venous access devices.

Catheters should be inserted by experienced personnel, and complication rates fall with increasing experience in catheter insertion. Increasingly, long-term central venous access devices are placed with interventional radiology techniques. These image-guided techniques have a 99% success rate at a lower cost than surgical placement and with a comparably low infection rate. Placement using interventional radiology is often obtainable in a more timely manner than with surgical placement. If the chest wall or the vessels of the upper body are not usable, an alternative site is the inferior vena cava, which is accessed through the femoral or saphenous vein or by a translumbar approach directly into the inferior vena cava.

Ports

Ports are inserted with surgical or interventional radiology techniques into the antecubital fossa or the chest or abdominal wall with the patient under local anesthesia. If possible, the port should be placed in the nondominant arm (or in the side of the chest near the nondominant arm) to minimize the probability of needle dislodgment or coring of the port septum during continuous access.

The chest wall ports are placed into a subcutaneous pocket in the infraclavicular space, and the attached catheter is placed under fluoroscopic guidance into the subclavian, jugular, or cephalic vein and threaded through the superior vena cava to the junction with the right atrium (see Fig. 89-2). No portion of the device remains visible.

DEVICE MANAGEMENT

Catheters

Care of nontunneled and tunneled catheters is begun by the nurses and later taught to patients and their families. To minimize infectious complications, it is preferable to assign this responsibility (as well as infusions and blood sampling through the catheter) to nurses who are expert in catheter care and use. Standard procedures are available and should be adopted by each institution, to be followed by all who care for the patient.

Patient and family education in catheter care is required to maintain patency, to prevent damage to the external portion of the catheter, to prevent air embolization, and to reduce the risk for infection. Instructions should cover permissible activities, techniques of dressing changes, heparin instillation, and changing the Luer-Lok plug, as well as emergency care in the event of damage to the external portion of the catheter. This educational program should be started well in advance of patient discharge to ensure patient and family competence; it may be reinforced by an educational booklet, by attendance at a "hands-on" class, or by nurses sent into the home, at least initially, to verify compliance with procedures. Patients with a catheter or port in place should be given written information about the device, as well as a medical alert card, necklace, or bracelet indicating the device's location, the type of access, and a person to contact if problems arise.

Dressing changes for surgically inserted catheters require a sterile technique for 2 weeks after insertion, until fibrous growth into the cuff is complete. The catheter exit site is cleaned with an antiseptic solution. Povidone iodine has been commonly used in the United States, but chlorhexidine-based solutions may be preferable because they have been shown to reduce the risk for catheter colonization and catheter-related bloodstream infection (CRBSI).

A formulation of chlorhexidine with isopropyl alcohol has been approved by the U.S. Food and Drug Administration (FDA) for catheter site use and has been available for over-the-counter purchase since 2005. Sterile dressing changes are done every 3 to 7 days for 2 to 3 weeks after insertion, depending on the dressing materials used (more frequently for povidone iodine and less frequently for chlorhexidine).

The type of dressing, if any, needed to cover the site once the incision is healed is controversial. One prospective, randomized study indicated that when a rigorous cleaning protocol was followed, the incidence of site infection was no different regardless of whether standard gauze and povidone iodine, a transparent polyurethane dressing (e.g., OpSite, Tegaderm) permeable to water vapor, or no dressing was applied. Current guidelines recommend use of either sterile gauze or sterile, transparent, semipermeable dressing. A chlorhexidine-impregnated sponge dressing decreased the risk for catheter colonization and catheter-related infection in a prospective, randomized study. Their use is recommended for temporary short-term catheters in patients older than 2 months of age if the central line–associated bloodstream infection (CLABSI) rate is not decreasing despite adherence to basic prevention measures.

Dressings should be replaced whenever damp, loosened, or soiled. Moisture vapor-occlusive dressings are strongly recommended for patients with tracheostomies or open wounds near the catheter site. After 2 to 3 weeks, a clean technique is used in some institutions for nonneutropenic patients, and an adhesive bandage or small gauze dressing may be used to cover the exit site. More complete guidelines for access and maintenance of surgically inserted catheters are available.

Except with dialysis catheters, the use of antibiotic or iodine ointment to prevent infection at the catheter insertion site is not recommended, because of the potential for promotion of fungal infection and antibiotic resistance.

As a rule, the catheter is not considered to be securely anchored in place until 10 to 21 days after placement, although insertion site stitches are usually removed after 10 days. Even then, catheters should not be allowed to hang freely; instead, they should be taped to the chest wall or inserted into a brassiere cup. A clamp should be immediately available in the event of any breaks in the line. Some manufacturers include a clamp placed on the catheter. Patients should be advised to keep the catheter out of the reach of pets or small children, who could inadvertently dislodge the catheter by pulling on it.

Because a thrombus on the catheter tip can be the nidus for a bacterial or fungal infection, every effort should be made to prevent one from forming. Heparin should be instilled in nonvalved catheters after each episode of blood drawing or blood product administration and when the catheters are not being used for intravenous therapy. A wide variety of flushing regimens are reported in the literature with various concentrations and volumes of heparin and frequencies, although few regimens are based on research. Based on a review of the available research-based practice, a flushing regimen of 5 mL of 10 units/mL heparin one or two times per week is recommended. In one study, twice-weekly flushing, rather than daily, resulted in a 33% decrease in catheter-related bacteremia without an increase in thrombus or intraluminal clots. A further decrease in intraluminal infection rate in immunocompromised, nonneutropenic patients with tunneled catheters may be provided by adding vancomycin to the heparin flush. However, the antibiotic flush has been associated with increased antibiotic resistance and allergic reactions. Recommendations for PICC flushes range from 3 mL of heparin (100 units/mL daily) to 3 mL of 10 units/mL three times per week. The dose of heparin used to flush the catheter should not alter the patient's clotting factors. At a minimum, the flush should be twice the volume of the catheter plus any add-on devices.

The use of the heparin flush alters coagulation tests if blood is drawn through the catheter. The first 10-mL sample shows spurious elevations in levels of fibrin degradation products, prothrombin times, partial thromboplastin times, and spuriously low fibrinogen levels. Elevations in the prothrombin time and partial thromboplastin time will persist in the second 10-mL sample.

Valved catheters require a 5-mL to 10-mL normal saline flush weekly or after use. The Groshong-type valve can be kept in the open position by small clots or solid residues from medications, allowing blood to flow back into the catheter, forming a clot.

Investigators have examined the potential role for using thrombophylaxis for cancer patients with central venous access devices. The most recent data show no proven role for using mini-dose warfarin or low-molecular-weight heparin despite being shown to be safe and well tolerated in such patients with hematologic malignancies and pronounced thrombocytopenia. Some experts still advocate thrombophylaxis for patients at high risk for developing catheter-related complications. Dalteparin prophylaxis using 5000 international units once daily did not reduce frequency of central venous catheter-related thrombosis in cancer patients.

More detailed guidelines for nursing education and practice regarding maintenance of catheters are available.[7]

Ports

Ports can be used immediately after insertion. However, because postoperative edema and discomfort often delay any attempts at access for several days, patients should be sent from the operating room with the Huber needle in place and ready for use. Incisions

should have a dressing until the sutures are removed. If skin closure is accomplished with surgical adhesive, a dressing is not required after the operative day and the site may get wet after the first day, although it may be preferable to delay this longer.

To access a port that has no needle in place, the skin is prepared with antiseptic; povidone-iodine or chlorhexidine is recommended. Anesthetic agents that may be applied include ice or a cold pack for a few minutes, a freezing agent (ethylene dichloride), or topical anesthetic cream (EMLA), which must be applied 1 hour before needle insertion. A 19- to 22-gauge Huber needle (depending on the product to be infused) is inserted (see Fig. 89-2). This steel needle has a deflected point and side opening, designed to prevent coring of the septum. The needle is primed with saline, attached to a saline-containing syringe, and then inserted perpendicular to the septum. Correct placement in the port can be confirmed by aspiration for blood return. However, aspiration for blood may be unsuccessful, usually because the needle is misaligned or because a fibrin sheath has formed, creating a ball-valve effect. If there is no swelling, the port flows well to gravity and there is no other symptom to suggest a potential problem, the needle can be assumed to be correctly placed and the port safely used for nonvesicant infusions. If access is difficult, it may be helpful to palpate the site while comparing it with a recent radiograph. Access may also be accomplished under fluoroscopy if standard technique by palpation is unsuccessful. Detailed accessing procedures for drawing blood and for administering drugs and blood products are available.[7] During use, the port is covered with a sterile dressing. A transparent, occlusive dressing may be preferable to help stabilize the needle and prevent inadvertent dislodgment. Dressing guidelines for external catheters can be followed for ports. The needle is changed weekly. After each use or every 4 weeks, implanted access devices also require heparin instillation or a 20-mL saline flush for valved ports. A variety of heparin concentrations and volumes have been reported. Use and maintenance of the peripheral port are essentially the same as for ports implanted in the chest wall. Ongoing discussion continues regarding optimal maintenance procedures.

DEVICE REMOVAL

Device removal should be considered when it is no longer needed, in part to minimize risks for thrombosis and infection, as well as when complications arise. Nontunneled catheters are removed nonsurgically by applying steady tension. If the catheter appears to be stuck, measures should be taken to reverse vasospasm (e.g., application of warm compresses, flushing with normal saline). If the catheter remains fixed, a cutdown on the venous insertion site to remove thrombotic material is usually effective. Tunneled catheters should be removed by surgical cutdown around the cuff, which should be entirely removed. For cases in which bacterial studies of the internal catheter tip are desired, blunt dissection of the cuff, with transection of the catheter above it and sterile removal of its inner portion, can be performed under local anesthesia. Ports, including the reservoir, catheter, and all suture materials, are removed surgically with the patient under local anesthesia. PICCs can be removed by nursing staff at the bedside.

COMPLICATIONS

Complications of indwelling vascular access devices include those occurring during the initial placement, cutaneous reactions to standard care materials, mechanical problems, phlebitis and infiltration, infection, hemorrhage, catheter occlusion of nonthrombotic or thrombotic origin, and vesicant drug extravasation.

Children

Pediatric-specific studies have cited age (younger than 5 years in one study, younger than 2 years in another), use of multilumen catheters, absence of skin exit site suture, and platelet transfusion at time of insertion as the most common reasons for premature catheter removal. Pediatric cancer patients with external catheters have had more complications requiring device removal compared with port devices from infectious causes and occlusive events.

Initial Placement

Approximately 1% to 4% of patients in whom a central catheter is inserted percutaneously develop a pneumothorax. Other surgical complications include hemothorax, arterial venous or cardiac perforation, brachial plexus injury, air embolism, and pericardial tamponade. After placement of PICCs, the distal tip can be malpositioned and requires replacement or repositioning of the PICC.

Cutaneous Reactions

Approximately 5% of patients develop skin reactions to the products used in caring for the devices. These reactions include erythema, urticaria, exanthematous or purpuric eruptions, and skin peeling or abrasion. These skin abnormalities must be distinguished from exit-site infections by appropriate culturing of the site for bacteria. In uninfected patients, changes in the dressing material, tape, and local skin care regimen are effective in reversing the skin abnormalities. Skin reactions may be compounded when the patient has received radiation therapy to the area covered by the dressing.

Skin erosion over the implanted ports, caused by malnutrition, separated wound edges, local infection, or carcinoma metastatic to the skin, occurs in 3% to 10% of patients, and removal of the port is always required. In very thin patients, the risk for erosion may be lower when a low profile rather than standard depth port is used.

MECHANICAL PROBLEMS

Catheters

Damage to the external segment of the tunneled catheter includes separation between the Luer-Lok connection and the tubing; cracks caused by repeated cross-clamping, if rubber-tipped forceps are not used; and cuts made by scissors mistaken for clamps. Catheter repair kits should therefore be available. Patients should also be instructed to contact their physicians or the oncology nursing staff immediately if the catheter is damaged at home.

Catheter fractures and emboli occur in about 0.2% of subclavian catheter insertions. The internal portion of the catheter usually fractures at the junction of the clavicle and first rib, and angiographic studies reveal the pathognomonic catheter pinch-off sign. Catheter pinch-off occurs when catheters inserted medially to the midclavicular line become compressed by shoulder movements. The resulting fragments migrate to the right heart or pulmonary artery and cause thromboses, cardiac arrhythmias, and fatal emboli; extravasation of fluids, lymph, or vesicant agents may also ensue at the site of breakage. Patients complain of pain or swelling at the port or vein insertion site, chest pain, cough, or palpitations. Catheter fragments are usually retrievable with interventional radiology techniques.

PICC lines can also embolize if they are sheared by needles, sutures, or surgical instruments while they are being inserted. If the fragment cannot be prevented from migrating more proximally by applying local pressure at the break site or by placing a tourniquet proximal to the site, it can be removed by venous cutdown. If it has migrated, percutaneous techniques or a thoracotomy will be required, but some fragments are never retrieved. Apheresis catheters placed in the inferior vena cava can also develop fractures of the external segment, with visible leakage, and they can be repaired using the kits mentioned earlier. Fractures of the internal portion of the catheter,

however, require catheter removal. Most of these fractures can be detected by injecting radiologic contrast material through them and observing the flow of the dye fluoroscopically.

Ports

The port may migrate or flip within its pocket because of defective suturing or excessive arm movement or because of manipulation by the patient. This malposition can be surgically corrected.

PHLEBITIS AND INFILTRATION

Phlebitis and infiltration are uncommon complications associated with properly positioned centrally placed access devices but are noted with the peripheral port and in 2.2% to 23% of patients with PICCs. Cancer patients with PICCs have had comparable rates of phlebitis. In a randomized, controlled trial comparing the complications associated with steel needles, short Teflon catheters and PICCs, these findings were noted: PICCs were associated with the highest incidence of phlebitis (27%) and the lowest incidence of infiltration (8.1%); steel needles were associated with the lowest incidence of phlebitis (8%) and the highest incidence of infiltration (45%); Teflon catheters ranked in between PICCs and steel needles, with incidence of phlebitis and infiltration at 19% to 20%. An aseptic phlebitis may occur within the first week after PICC insertion. It can be prevented by administration of nonsteroidal antiinflammatory agents or by treatment with warm compresses applied for 48 to 72 hours. Catheter removal is usually not required.

INFECTION

For a list of important infection-related terms and definitions, see box on Infection.

Incidence

Intravascular devices (IVDs) are the most important cause of hospital-acquired bloodstream infections and are associated with increased hospital costs and length of stay.[6] When expressed as infection rate per 1000 IVD-days, the highest risk exists with peripheral catheters placed by surgical cutdown, followed by peripheral steel needles. The lowest rates of infection are associated with subcutaneous venous ports, either central or peripheral. Cuffed and uncuffed tunneled catheters have lower risks for infection than do untunneled catheters. Cuffed devices share the lower rates of infection with outpatient, PICC and peripheral IV catheters, as well as ports.[9] Increasingly, standardized infection control procedures are being used to help reduce CRBSI, as published by the Centers for Disease Control and Prevention (CDC) in 2011.[9]

Between 1% and 9% of patients experience infection at the exit site, tunnel, or pocket. Exit-site infections appear to be responsible for up to 45.5%; tunnel infections, for up to 22% of all catheter-related infections. Most CRBSIs for catheters in place for less than 10 days are of cutaneous origin from the insertion site, and the organisms gain access extraluminally, whereas for long-term devices in place for more than 10 days, luminal colonization is the major mechanism of CRBSI. Prophylactic antibiotics have not consistently proven beneficial in preventing these infections, and their use is not generally recommended. Catheters and cuffs coated or impregnated with antimicrobial or antiseptic show some promise in decreasing CRBSI and remain an area of investigation. Metaanalyses of randomized controlled trials suggest that these catheters may reduce the risk for CRBSI.[10] The compounds that have been used are minocycline/rifampin and chlorhexidine/silver sulfadiazine, but there are concerns about the emergence of resistant organisms with these catheters. The evidence supporting use of these compounds to reduce risk for CRBSI is equivocal for short-term CVCs and inconclusive for long-term CVCs in place longer than 10 days. Current CDC guidelines recommend use of a chlorhexidine/silver sulfadiazine or minocycline/rifampin–impregnated CVC in patients whose catheter is expected to remain in place for more than 5 days if CLABSI rates are not decreasing at the institution despite a comprehensive strategy.[10]

Infections are generally prevented by meticulous insertion and maintenance techniques. PICCs inserted at the bedside show a higher rate of infection than do those inserted by interventional radiologists, probably because of insertion conditions (aseptic technique at the bedside versus sterile technique in the interventional radiology suite). With maximal barrier precautions, however, catheter insertion at the bedside is associated with no higher infection incidence than is placement in the operating room.

The incidence of device-associated infection varies depending on the type of device inserted and the medical disorder of the patient. Overall, the incidence of midline catheter-associated infections is low and that of tunneled catheters is approximately 1 to 3 per 1000 days of patient use. Cumulative incidence of PICC-related blood stream infections is 1.1 per 1000 PICC-days (range 0.9 to 1.3), but higher in the inpatient setting (2.1 per 1000 PICC-days).[6] The use of multiple-lumen catheters probably increases the infection rate significantly. In one study, the sepsis rate for double- and triple-lumen catheters was comparable at 13% and 16%, respectively, but infections occurred significantly earlier with the triple-lumen catheters (a mean of 54 days versus 141). Fewer catheter-related bacteremias

Infection

Definitions

The Centers for Disease Control and Prevention (CDC) has established the following definitions for catheter- and port-associated infections.[8]

Localized catheter colonization: Significant growth of a microorganism (greater than 15 CFU) from the catheter tip, subcutaneous segment of the catheter, or catheter hub.

Exit-site infection: Erythema, or induration within 2 cm of the catheter exit site, in the absence of concomitant bloodstream infection (BSI) and without concomitant purulence.

Clinical exit-site infection (or tunnel infection): Tenderness, erythema, or site induration of more than 2 cm from the catheter exit site along the subcutaneous tract of a tunneled catheter (i.e., Hickman or Broviac) in the absence of concomitant BSI.

Pocket infection: Purulent fluid in the pocket of a totally implanted intravascular catheter that may or may not be associated with spontaneous rupture and drainage or necrosis of the overlaying skin in the absence of concomitant BSI.

Infusate-related bloodstream infection: Concordant growth of the same organism from the infusate and blood cultures (preferably percutaneously drawn) with no other identifiable source of infection.

Catheter-related bloodstream infection: Bacteremia or fungemia in a patient with an intravascular catheter with at least one positive blood culture obtained from a peripheral vein, clinical manifestations of infections (e.g., fever, chills, or hypotension) and no apparent source for the BSI except the catheter. One of the following should be present: a positive semiquantitative (greater than 15 CFU/catheter segment) or quantitative (greater than 10^2 CFU/catheter segment) culture whereby the same organism (species and antibiogram) is isolated from the catheter segment and peripheral blood; simultaneous quantitative blood cultures with a 3:1 ratio for CVC versus peripheral; or differential period of CVC culture versus peripheral blood culture positivity of more than 2 hours.

occur with totally implantable venous access devices (ports) than with tunneled catheters. Several social conditions contribute to greater risk for indwelling venous access device infections, including poor hygiene and lower socioeconomic status. For pediatric cancer patients, increased risk for infection is associated with language barriers that limit parental understanding of how to care for the CVC. The infection rate with implanted ports is lower, 0.0 to 0.1 per 1000 patient-days for ports inserted on the chest wall.

Neutropenic patients, particularly with a hematologic malignancy, have a near 14% greater risk for developing CRBSI. Patients with HIV infection and those receiving a bone marrow transplant have significantly higher rates of catheter- and port-related infections. Patients with hemophilia had a pooled incidence of 0.66 infections per 1000 CVAD days; age greater than 6 years and the use of fully implanted CVADs significantly reduced the risk for infection, whereas the presence of inhibitors significantly increased the risk.[4] For adult patients with sickle cell disease, bacterial infections are a leading cause of mortality, and one study cited a greater incidence of bloodstream infections in younger patients with hemoglobin S (HbS) disease, on transfusion and/or desferrioxamine programs, and in patients with a central venous catheter. Of all episodes of bloodstream infections in these sickle cell patients, 41% were attributed to a venous catheter, and device infection occurred in 77% of patients with tunneled implantable ports.[11]

Patients with acute leukemia have higher rates of infection than do patients with other types of cancer. This is in part because of the higher occurrence of catheter manipulation associated with treatment for acute leukemia; longer periods of neutropenia may also be a factor. Patients with acute leukemia are also at higher risk for developing septicemia as a consequence of prolonged neutropenia. The presence of a CVC increases the risk for infection in the early phases of low-intensity treatment for acute lymphoblastic leukemia (ALL) in pediatric patients.

Organisms

The most common organisms associated with hospital-acquired CRBSI are coagulase-negative staphylococci (37%), *Staphylococcus aureus* (13%), enterococci (13%), and *Candida* (8%).[5] Staphylococcal and candidal organisms adhere to the fibrin or fibronectin sheaths surrounding indwelling catheters, and some staphylococci produce a "slime" that further promotes bacterial proliferation on the catheter surface as the slime protects the organisms from phagocytes, antibodies, and antibiotics. Catheters with siliconized latex and polyvinyl chloride catheters have been shown to have more bacterial adherence than catheters made from other materials. Coagulase-negative staphylococci also adhere to polymer surfaces more readily than other organisms. Other gram-negative organisms, including *Pseudomonas,* also cause infection. *Pseudomonas* is particularly problematic when showering or swimming has been allowed. *Xanthomonas (Stenotrophomonas maltophilia)* infections can be particularly troublesome because of increasing multidrug resistance, formation of biofilm, and their prevalence in immediate post-CVC insertion setting and longer-term indwelling setting. They are more prevalent in cancer patients who have these three independent risk factors: pneumonia, neutropenia at onset of bacteremia, and admission to ICU within 1 month of onset of bacteremia.

A reported 5.4% to 9.9% of infecting organisms are fungal, three-fourths of which are *Candida* species, although nosocomially acquired cutaneous infections with *Aspergillus flavus* have been noted at the sites of insertion and along the subcutaneous tract of Hickman catheters. *Candida* infections in the oncology or bone marrow transplantation population are associated with a high mortality rate. Infection with drug-resistant non–*C. albicans* is increasing in frequency in patients with CVCs. In HIV-positive patients, staphylococci are the most common infecting organisms, but *Pseudomonas* species causing fatal septicemia, other gram-negative organisms, and lactobacilli are increasingly reported. Septicemia due to catheter infection by typical or atypical *Mycobacterium* species has also been noted.

S. aureus is the most common organism infecting ports of patients with hemophilia, especially those with inhibitors. Other implicated organisms in hemophilia patients include *Pseudomonas* species, *Enterobacter cloacae, Escherichia coli, Klebsiella* species, *Serratia liquefaciens,* and *Acinetobacter* species.

In adult sickle cell patients with CVADs, infections were seen with *S. aureus, E. coli, Acinetobacter* species, and *Pseudomonas*.

INDICATIONS FOR REMOVAL

Debate continues over cost-effectiveness and salvage rates for catheters once CRBSI is documented.

Exit-Site and Tunnel Infections

Exit-site infections caused by bacteria rarely require catheter removal for resolution, because most (69% to 100%) respond to antibiotics alone. These infections are most often caused by *S. epidermidis*. Similarly, with implanted ports, infections of the skin pocket have been found to resolve in about 70% of cases without removal of the device.

Tunnel infections or port pocket abscess, by contrast, usually do not respond to antibiotics; they have been reported to resolve without catheter removal in only 25% to 50% of cases. Catheters were removed from all patients with cutaneous *Aspergillus* infection, six of whom recovered after antifungal therapy and local wound care (see box on Infectious Indications for Device Removal). Resolution of leukopenia was required for infection resolution. Similarly, *Mycobacterium* and atypical mycobacterial infection of the tunnel or exit site requires catheter removal as well as excision of infected tissue.

Septicemia

In a patient with septicemia and a catheter or port in place, it is often difficult to determine whether the catheter itself is truly infected or whether the bacteremia is from another source. Quantitative culture is the most sensitive technique, but the semiquantitative roll-plate method is most often used to diagnose catheter-related infections. Both, however, require that the catheter be removed. Quantitative blood culture techniques can be used with a catheter in place. If the

Simon A, Bode U, Beutel K: Diagnosis and treatment of catheter-related infections in paediatric oncology: An update. *Clin Microbiol Infect* 12:606, 2006.

colony count in cultures of blood drawn from the catheter is 5 to 10 times greater than the count in cultures of peripherally drawn blood, the infection is very likely to be catheter-related.[6] For presumed *Candida* infection, it has been suggested that molecular analyses of material from various anatomic sites may help determine the true source of the infection (e.g., sputum versus blood) and prevent needless device removal.

In assessing the cause of infection in a patient with a port, care must be taken not to draw blood for culture through a possibly infected port pocket unless the Huber needle is already in place. Accessing a port through an infected port pocket could introduce organisms into the reservoir and from there into the systemic circulation. To determine whether a port is truly infected, material within the port should also be cultured after it is removed.

When another source is definitely identified, however, the catheters can usually be left in place, because the incidence of hematogenous colonization is low (1%). When there is no thrombophlebitis, even when the catheter is believed to be the source of the infection, or when no source is clearly identified, resolution of bacterial septicemia occurs in 75% of episodes without removal of the catheter.

The possibility of clearing the infection without catheter removal, however, is much lower in patients with septic thrombophlebitis, occluded catheters, exit-site infections, fungal septicemia, or bacteremia due to *S. aureus, Xanthomonas,* or *Pseudomonas*. In other studies, children and adults with catheter-related candidemia had higher rates of treatment failure, secondary complications, and mortality if the catheters were left in place during antifungal treatment. Line removal is recommended when the fungemia is line-related. Successful surgical removal of right atrial thrombi superinfected with *C. tropicalis* or *S. epidermidis* has been reported in several patients, including those with sickle cell anemia. Replacement of catheters on the contralateral side within 1 to 3 days after removal is usually not associated with recurrent catheter infection.

Antibiotic-lock therapy (ALT), with and without concomitant parenteral therapy, has shown success in the prevention and treatment of catheter-related bacteremia when intraluminal infection is likely. In 21 trials of ALT for CRBSI involving long-term catheters, catheter salvage without relapse occurred in 77% of episodes.[8] ALT involves instillation of an antibiotic solution, at a concentration of 1 to 5 mg/mL, into the catheter hub. The solution remains in place for a predetermined amount of time and is withdrawn before the next dose of intravenous antibiotic or medication. ALT itself allows much higher concentration and longer duration of activity of antibiotics at the colonized intraluminal/infected catheter surface without the potential side effects of systemic exposure. It also helps eradicate biofilm-forming bacteria. The goals include prolonging catheter life and reducing patient morbidity and costs associated with catheter-related infections. ALT can also be an option for salvaging venous access when venous access is otherwise limited, and patients have a CRBSI that has not progressed to septicemia and does not involve tissue infection at insertion or tunnel site. ALT has been less effective for treating infections of implantable ports than infections from other types of CVCs.

The most efficacious concentration and duration of ALT remains unclear, although the Infectious Disease Society of America (IDSA) recommends catheter locking for 14 days, with daily changing, in addition to 7- to 14-day systemic administration of antibacterial treatment for uncomplicated catheter-related bacteremias.[8] It should be combined with systemic treatment for at least the first 72 hours. At this time, no evidence-based recommendations are available regarding optimal concentration or intraluminal dwell time. The IDSA does recommend that for vancomycin, concentration should be at least 1000 times higher than the MIC of the microorganism involved and the lock therapy be changed every 48 hours. Combination ALT, including minocycline/vancomycin, minocycline/rifampin, vancomycin/rifampin, is more effective in vitro against biofilm-forming coagulase negative staphylococci. M-EDTA (minocycline plus ethylenediaminetetraacetic acid, or EDTA) has demonstrated activity against gram-positive and gram-negative bacteria, as well as *Candida* species. A randomized control trial is needed to judge its efficacy for long-term CVC infections. In general, ALT has not been as successful for fungal infections. Catheters should be removed in the case of a CRBSI that is due to *S. aureus* or *Candida*.

In existing studies, several factors limit how best to use ALT. These include a lack of data from large, randomized control trials, comparing the efficacy of ALT to systemic antibiotics for treatment of line infections. Additionally, differences in antibiotics used for ALT, heterogeneity in study populations tested, presence or absence of heparin, and inconsistent definitions of catheter-related sepsis further complicate the generalizability of existing data. Overall, it appears ALT alone shortens the length of hospital stay, compared with systemic antibiotic therapy for treatment of line infections.

Hemorrhage

Despite the frequent occurrence of thrombocytopenia in patients with indwelling access devices, few bleeding complications are associated with their placement or with the placement of the larger apheresis catheters. Capillary fragility from prolonged steroid therapy, however, may contribute to perioperative hemorrhage. Pressure dressings and platelet transfusions given pre- and postoperatively usually control local oozing. However, in patients with uncontrolled disseminated intravascular coagulation, excessive bleeding has occurred with catheter insertion; many groups consider disseminated intravascular coagulation an absolute contraindication to catheter placement. In contrast, catheters and ports have been placed without excessive bleeding in patients with hemophilia when factor levels were maintained at 100% preoperatively and for 5 days postoperatively.

CATHETER OCCLUSION

Nonthrombotic Causes

Although a clot is the most common cause of occlusion, inability to aspirate blood from the port or catheter does not necessarily mean that it has clotted. Other causes include a malpositioned Huber needle, catheter abutment against the wall of the vein, catheter kinking, catheter pinch-off, precipitation of drug solutions in the catheter lumen, development of fibrin sheaths, and catheter migration with resultant malposition of the tip. Tip migration secondary to growth, especially during periods of growth spurts, is a problem specific to the pediatric population. Tip placement should be evaluated regularly as the child grows in height. Algorithms for the evaluation and treatment of catheter occlusion are available.

Catheter abutment may resolve by changing the patient's position or by performing a Valsalva maneuver. Pinch-off occurs when the catheter is placed too medially and is compressed between the clavicle and first rib. Repositioning patients with catheter pinch-off often relieves the compression and reestablishes catheter function; however, this is impractical for long-term catheter use, and the catheter usually needs to be repositioned.

Precipitation of incompatible solutions occurs with etoposide, calcium, diazepam, phenytoin, heparin, and total parenteral nutrition (TPN) infusions. Catheter blockage due to precipitation of calcium carbonate was reported at 8 to 24 weeks in 50% of patients with metastatic colon carcinoma receiving once-weekly 24-hour infusions of high-dose 5-fluorouracil (2600 mg/m^2) and leucovorin (500 mg/m^2). Although precipitates may occasionally resolve with warm soaks over the tunnel site, dilute solutions of hydrochloric acid have successfully cleared precipitates from TPN solutions alone or with lipids, etoposide, calcium salts plus sodium bicarbonate, and heparin with incompatible antibiotics. A solution of 0.1 normal HCl to equal the volume of the catheter is instilled and allowed to stand for 20 to 60 minutes. Febrile reactions may occur. Sodium bicarbonate has resolved phenytoin, ticarcillin clavulanate, and oxacillin precipitates. Lipid buildup or occlusions may respond to 70% ethanol instilled for 1 to 2 hours or sodium hydroxide (0.1 N).

Fibrin starts depositing on a catheter within 24 hours of insertion and may be present in as many as 67% of catheters. Withdrawal occlusion secondary to the ball-valve effect of a fibrin sheath accounts for 10% to 57% of catheter occlusions. The fibrin sleeve itself may embolize. Presence of a fibrin sheath increases the risk for infection. Techniques using nonlytic and lytic agents to remove the sheaths have been described. Lytic therapy is discussed later.

Maintaining correct position of the catheter tip can help prevent numerous complications. Catheter migration occurs in 5.5% to 29% of insertions when the subclavian approach is used. Review of the patient's chest radiograph most commonly shows the malpositioned catheter tip to be in the ipsilateral jugular vein, the axillary vein, or the contralateral brachiocephalic vein. When the catheter is in the jugular vein, patients often complain of a whooshing or gurgling sound when the line is flushed. Venous thrombosis can occur as a result of damage to the endothelium, turbulence created by the tip at venous branching points, or insufficient dilution of infusate that causes thrombophlebitis. Catheter erosion through the vessel or cardiac wall can produce extravasation, fistula formation, and pericardial tamponade. Catheters inserted into the left internal jugular or subclavian veins have also eroded into the bronchi; the ensuing venobronchial fistulas were associated with cough, pneumonia, and respiratory failure. Repositioning the catheter can usually be accomplished by interventional radiologists without catheter removal.

PICC malposition is common. PICCs should be well secured at the insertion site to prevent "pistoning" in the vein, which increases the possibility of phlebitis or infection. The catheters can usually be repositioned by trained nurses using simple bedside techniques. Migration of the apheresis catheter in the subcutaneous space also manifests as access failure, because the catheter tip is pulled back to the wall of the inferior vena cava or out of the intravascular space. Intravascular malposition can be corrected by tip deflectors or J-wires.

Thrombosis

Thrombosis can occur in the catheter itself or in the superior vena cava or veins of the upper extremity. While asymptomatic thromboses have been reported in rates up to 60%, most recent studies show an incidence of symptomatic catheter-related deep venous thrombosis (DVT) to be lower than 6%, with similar rates of catheter-related DVT for access achieved through the subclavian and jugular veins. Almost all central indwelling venous access devices become coated with a fibrin sheath within days of insertion, and accordingly, the majority of CVC-related thrombi arise within 30 days of initial placement.[12]

Several potential risk factors for indwelling access catheters in cancer patients have been studied. In a metaanalysis of cancer patients with PICCs or implanted ports, improper catheter tip locations, history of DVT, and subclavian venipuncture insertion technique were associated with increased thrombosis risk.[13] Catheter tip placement has been implicated in the formation of extraluminal thrombosis, with location high in the SVC accounting for a greater incidence of thrombosis than placement in the distal SVC or right atrium (62% to 78% versus 16%). Thrombogenicity was shown to be lesser in silicone and polyurethane CVC compared with polyvinylchloride and polyethylene CVC. Additional risk factors include greater than one attempt at insertion, a previous catheter (with vessel wall trauma and endothelial damage), ovarian cancer, and left-sided insertion site. There were no clear differences in the rate of CVC-related thrombosis with regard to chemotherapy administration methods (push/bolus versus infusion). A threefold increased rate of catheter failure from thrombosis was noted for triple-lumen compared with double-lumen Hickman catheters.

A bidirectional impact of infection and thrombosis has been well documented. One study reported an RR of 17 for developing clinical thrombosis manifestations after an episode of CVC-related infection, with 57% risk after an episode of CVC-associated septicemia versus 27% risk in patients with local CVC-infection only. Even in those patients with subclinical thrombosis, CVC-related infection occurred in 92%, compared with 7% without thrombosis.

Special Populations

For pediatric patients, those who have ALL and are receiving L-asparaginase and external catheters had 3.9-fold higher risk for CVC-thrombosis compared with children who had implanted ports. Children with leukemia, neuroblastoma, and Hodgkin lymphoma with FVL, protein C deficiency, and high lipoprotein (a) levels had a significant association with symptomatic CVC-related thrombosis.

For hemophilia patients, thrombosis has been a relatively rare event. A pooled thrombosis incidence of 0.056 per 1000 CVAD-days has been cited, with no cases documented of superior vena cava syndrome or catheter-associated pulmonary embolism. Furthermore, neither age nor the presence of inhibitors significantly altered the thrombotic incidence. However, because thrombotic complications have been documented less extensively for hemophiliac patients (especially compared with infectious complications), the true extent of subclinical and clinical complications is unknown.

For sickle cell patients, although the condition itself is considered hypercoagulable, it remains unclear how this, coupled with the presence of indwelling access devices, affects the incidence of clinically significant and symptomatic thrombosis.

Patients with multiple myeloma are likely at increased risk for venous thrombosis in the setting of hyperviscosity and treatment with thalidomide or lenalidomide-containing regimens; placing central venous access devices likely increases the risk.[14] Patients with acute promyelocytic leukemia (APML) and high-grade lymphoma also appear to be at higher risk for venous thrombosis.

Spontaneous upper extremity DVT (UEDVT) has been reported to be 2.6-fold to 2.8-fold more likely in patients with active cancer, with the additional presence of an indwelling venous access device increasing the risk further. Clinical UEDVT has been reported to occur in 0% to 9% of patients with chest ports and 2% to 30% with arm ports. Overall, CVADs account for 75% of all cases of UEDVT. Postphlebitic or postthrombotic syndrome following UEDVT among cancer patients range from 4% to 30%.

Most noninvasive methods used for diagnosis of catheter-related thrombosis and/or UEDVT, including duplex ultrasound, Doppler imaging, and plethysmography, have low sensitivity or have not been reliable. Color Doppler duplex sonography, however, has been shown to have sensitivity of 78% to 100% and specificity of 82% to 100% for diagnosis of UEDVT in the setting of peripheral UEDVT (e.g., jugular, distal subclavian, and axillary veins) and in symptomatic patients. Still, the presence of overlying bones may make the visualization and direct assessment via compression techniques difficult. Spiral computed tomography (CT) can be helpful for suspected catheter-related thrombosis involving the brachiocephalic vein or superior vena cava and for those with suspected pulmonary embolus. Magnetic resonance angiography has not proven to be a reliable alternative. Although venography is the gold standard, it is limited by its invasiveness and cost. If venous obstruction is demonstrated, intraluminal versus extraluminal obstruction may be further defined by venography if clinically warranted. In patients with prior central venous catheterization associated with deep venous thrombosis, preprocedural duplex ultrasound may be useful to predict the success of repeat catheter placement.[17]

THERAPY

The clinical significance and course of action are unclear in patients undergoing high-intensity antineoplastic therapy who develop asymptomatic subclavian, or innominate vein thromboses. The majority of catheter-related thromboses are asymptomatic. But patients with symptomatic UEDVT require therapy. They may develop septic thrombophlebitis, superior vena cava syndrome, major

long-term upper extremity disability, venous gangrene, and pulmonary emboli. In one retrospective study and review, 12% of patients with catheter-induced UEDVT developed pulmonary emboli, 40% of which occurred in patients receiving anticoagulant therapy. A 16% incidence of pulmonary emboli was found in a prospective study of patients with UEDVT in whom lung scans were performed within 24 hours of venographic diagnosis of the thrombosis.[15]

The National Comprehensive Cancer Network (NCCN) updated guidelines in 2011 for catheter-related UEDVT to help guide clinicians in evaluation and treatment.[16] These guidelines suggest that anticoagulation be used if DVT is present, if the catheter is required, and if there are no contraindications to anticoagulation. Suggested duration of therapy includes all time with the catheter in place or for 3 months, whichever period is longer. If DVT symptoms or presence of clot persist despite this therapy, the catheter should be removed. If anticoagulation is contraindicated, the catheter should be removed, the patient followed for any changes in relative contraindications, and anticoagulation initiated if otherwise permissible. Recommendations for the duration of anticoagulation are a minimum of 3 to 6 months for DVT, 6 to 12 months for pulmonary embolism (PE), and indefinitely if active cancer or persistent risk factors are present.

Management of Catheter Occlusion

Catheter occlusion, whether partial (sluggish flow), complete (inability to infuse or withdraw), or withdrawal type, have all been successfully treated with thrombolytic agents. Streptokinase, urokinase, and recombinant alteplase have all been used. Bolus thrombolytic therapy has reopened occluded catheters in 85% to 90% of episodes, and removal of the catheter is not usually required. No excessive bleeding has been noted, even in patients with hemophilia. Streptokinase is not commonly used because of its antigenic properties and associated allergic and anaphylactic reactions. Urokinase is available in recombinant form and has demonstrated efficacy for lysis of intraluminal thrombosis. Alteplase, a recombinant tissue plasminogen activator (tPA), has demonstrated superiority and is the preferred therapeutic option. A randomized trial comparing bolus urokinase (10,000 units) with tPA (2 mg) suggested marked superiority for tPA. Alteplase is available for catheter clearance in a 2 mg/2 mL vial, a volume sufficient to fill most catheter lumens. The technique is to fill the catheter lumen plus 0.2 mL to ensure that the tPA has close contact with any fibrin/clot at the distal tip of the catheter. It should dwell for 30 minutes to 2 hours and then be withdrawn. An additional dose of 2 mg can be repeated.

For extraluminal thrombi refractory to the bolus administration of thrombolytics, options to dissolve the thrombus include infusions of tPA, urokinase, or streptokinase through a catheter placed at or within the clot. High-dose streptokinase therapy is effective but expensive and is associated with a high incidence of bleeding. It is not recommended for patients with bleeding risks such as thrombocytopenia or mucositis. Infusion of urokinase for 24 to 72 hours restored catheter patency in 74% of patients (81% of those with clots present less than 7 days, and 56% of those with clots present more than 7 days). Infusion into the superficial venous circulation of the involved extremity was not effective. Although a low infusion concentration was used (5000 international units/hour of streptokinase or 500 to 2000 international units/kg/hour of urokinase), a systemic lytic state was documented. Urokinase infusion should not be undertaken in patients with contraindications to systemic fibrinolytic therapy. Another regimen for refractory clots involves an infusion of urokinase (40,000 units/hour) for 6 hours. This regimen led to dissolution of thrombi in 90% of patients; a repeat 6-hour infusion raised the dissolution rate to 95%. Infusions as short as 1 to 3 hours were successful in half of the cases studied. Addition of heparin to the 1- to 12-hour infusion did not improve the results. No bleeding complications were seen. In patients with catheter tips placed below the carina and not adherent to the venous wall, there is a low risk for reocclusion; these catheters need not be removed. Successful clot resolution with urokinase was reported for 50% to 87% of patients.

Once patency is restored, heparin is usually given for 5 to 7 days. Studies have shown an increased risk for recurrent DVT/PE in cancer patients. Currently there is no sound evidence to guide duration of anticoagulant therapy in these patients. The recommended practice is to continue treatment while there is evidence of active cancer and while the patient is receiving antineoplastics.

Vesicant Drug Extravasation

It is very unusual for a spontaneous leak to form in a large-bore catheter, but an attempt to irrigate an occluded catheter with a small syringe can cause a rupture through which the drug can extravasate. Occlusion of the catheter tip by a fibrin sheath may force drugs back up the sheath and through the exit site of the catheter. This so-called backtracking appears to be more common with percutaneously placed access devices.

Leaks may develop if the catheter is disconnected from the reservoir or if the catheter is punctured by mistake by the Huber needle. Outpatients using a port for continuous infusion of chemotherapy can experience drug extravasation if the Huber needle is dislodged from the septum. Even usually nonvesicant drugs can produce skin necrosis severe enough to warrant removal of the port. Use of the Port-A-Cath port, which has a thicker septum than the Mediport and Infus-A-Port devices, has been associated with only a 3% to 4% incidence of extravasation. The thickness of the septum has been postulated to be responsible for the low incidence of needle displacement noted with the Port-A-Cath, but no randomized trials have compared complications associated with the three devices. Selection of an appropriate length Huber needle and securing the needle to the chest wall with tape or a transparent occlusive dressing can provide some protection against dislodgment. If infusion pumps are used, attention must be paid to minimizing tension between the needle and the infusion tubing. See box on Treatment of Vesicant Drug Extravasation.[17]

CENTRAL NERVOUS SYSTEM ACCESS DEVICES

In patients with hematologic disorders, devices that permit chronic access to the CNS are useful for a variety of purposes. The available devices include temporary or permanent epidural catheters, ports with attached silicone elastomer catheters, implanted pumps with attached silicone elastomer catheters, and Ommaya reservoirs. The choice of device is determined by a number of factors, including available routes, duration of therapy, cost, efficacy for the therapy planned (e.g., antineoplastics versus pain medications), and the ability of the patient and family to care for the device.

Treatment of Vesicant Drug Extravasation

Treatment protocols for vesicant drug extravasation, including those recommended by the Oncology Nursing Society, are outlined in Table 89-2. When these protocols were used, 89% of vesicant extravasations were reported to resolve without additional therapy. However, 30% of anthracycline extravasations progressed to ulceration.

At many centers, it is recommended that an extravasation kit be kept in units in which vesicant drugs are given. The kit includes the appropriate medications, as well as order sheets preprinted for immediate use. For most vesicant drugs there is no proved antidote or local care measures. In general, whether an antidote is to be administered through the device or not, as much of the residual drug as possible should be aspirated from the needle, tubing, and tissues. Any antidote may then be administered. If swelling or pain persists for 72 to 96 hours after drug administration, a plastic surgeon should be consulted.

Table 89-2 Management of Vesicant Drug Extravasation

Drug Therapy	Local Care	Antidote Administration
ANTIBIOTICS		
Anthracyclines	Cold/ice pack for 15-20 min qid for 24-48 hr	Administer dexrazoxane (Totect) by IV in a vein away from the extravasation site. Infuse 1000 mg/m^2 within 6 hr of extravasation on day 1, 1000 mg/m^2 on day 2, and 500 mg/m^2 on day 3. Maximum daily dose is 2000 mg. Dimethyl sulfoxide (DMSO) should not be applied, and topical cooling (e.g., ice packs) should be removed 15 min before, and every 15 min during, administration.
Mitomycin-C	Cold/ice pack for 15-20 min qid for 24-48 hr	Topical application of 99% DMSO
VINCA ALKALOIDS		
Vincristine Vinblastine Vindesine Vinorelbine	For all vinca alkaloids, elevate and apply warm pack for 15-20 min at least qid for 24-48 hr	For vinca alkaloids extravasation, inject hyaluronidase subcutaneously, 1 to 6 mL of 150 units/mL solution into area of extravasation in clockwise manner, 1 mL of solution for 1 mL of extravasated drug.
TAXANE		
Paclitaxel	Cold/ice pack 15-20 min qid for 24-48 hr	
ALKYLATING AGENTS		
Mechlorethamine		Mix 1.2 mL of 25% sodium thiosulfate with 8.4 mL of sterile water for injection. Inject 2 mL of antidote for each 1 mg of drug extravasated.
Cisplatin (only if >20 mL of 0.5 mg/mL of concentration infiltrates)		Use sodium thiosulfate as described for mechlorethamine, 2 mL for each 100 mg of cisplatin infiltrated.

Catheters

Local anesthetics alone or combined with fentanyl, other opioids, and medications given through temporary epidural catheters (in place for less than 5 days), have successfully managed the pain and have improved oxygenation in children with sickle cell crisis. Chronic epidural access has become widely available since the development of a permanent epidural catheter that can be placed percutaneously. The catheters are most commonly used for pain control. Some catheters are one piece, and others consist of three pieces: two radiopaque silicone rubber catheters, an epidural segment (1.3-mm outer diameter), and an exteriorized line (3.1-mm outer diameter, 0.68-mm inner diameter) with an external Luer connector and a subcutaneous Dacron cuff and a splice segment that joins the two catheter segments.

Insertion

Catheter insertion is done under local anesthesia or conscious sedation. A paravertebral incision is made at the level of the L2 dorsal spine, and the epidural portion of the catheter is inserted through a 14-gauge Hustead or Tuohy needle to the desired spinal cord level. Epidural placement is verified by fluoroscopy and sensory blockade. The exteriorized line is then tunneled from a subcostal location on the midnipple line around to the lower end of the paravertebral incision, and the splice segment is secured to the two catheters and then to the supraspinous tissue to avoid kinking. A Millex-OR 0.22-μm filter is attached to the Luer connector, and a locking Luer injection cap is connected to the filter.

Access and Management

The catheter can be used immediately. Bolus doses can be given from a syringe, or the catheter can be connected to external pumps that deliver continuous infusion opioid with bolus rescue doses or combinations of opioids and local anesthetics. Only preservative-free solutions should be used. Wound and catheter exit-site cleaning and dressing changes are recommended until the last sutures are removed, usually after 3 weeks. After that, the exit site is cleaned every other day with povidone iodine, and the filter and injection port are changed weekly using sterile technique. More detailed nursing protocols for accessing and managing these catheters and for monitoring patients receiving epidural opioids are available. Patient and family education in catheter care can be effectively supplemented by referral to a home health care or hospice agency.

Complications

Some catheters can remain safely in place for months; however, in rare cases, even temporary catheters can cause serious infections if left in place for days to weeks. Complications include pain during injection, myoclonus, epidural fibrosis, obstruction and dislocation, and infection, as well as complications attributable to the opioids being infused. Patients whose catheters take longer to insert have higher infection rates. Exit-site and superficial catheter track infections occur infrequently (in approximately 10% of patients). The epidural space infection rate has been reported as 1 in 1702 days of catheter use, similar to the infection rate of 1 in 1045 per days of use associated with the Hickman catheter. *S. aureus* and *S. epidermidis* account for two-thirds of all infections. Exit-site and superficial catheter track infections may be cleared without catheter removal, but catheter removal is required for patients with deep catheter track or epidural infections (Table 89-3; also see box on Infectious Indications for Device Removal).

Epidural Ports and Implanted Pumps

Epidural ports (e.g., Port-A-Cath) and implanted pumps (e.g., Infusaid, Medtronic) have also been used to deliver bolus or continuous

Table 89-3 Important Pathogens in Central Venous Access Device–Related Infections

Pathogen	Source	Notable Complications
GRAM-POSITIVE BACTERIA		
S. epidermidis Coagulase-negative staphylococci	Hub; skin at exit site of device	Local/systemic and suppurative complications
Methicillin-resistant *Staphylococcus aureus* (MRSA)		
Enterococci, including vancomycin-resistant *Enterococcus* (VRE)	Intestines	Bacteremia, endocarditis
α-hemolytic streptococci	Oropharynx	
GRAM-NEGATIVE BACTERIA		
Pseudomonas aeruginosa	Hospital-acquired	
Klebsiella spp	Urinary Tract	

infusions of opioids into the epidural or intrathecal space to relieve pain of malignant or nonmalignant origin. Intrathecal devices that deliver pain medication have become increasingly sophisticated and offer an alternative for long-term treatment of persistent pain.[18] Consensus guidelines have been published on the selection of patients for intrathecal drug delivery.[19] Subarachnoid infusions using the implanted pumps are recommended as efficacious and cost-effective for patients with a relatively long life expectancy (more than 3 months).

Complications include those previously described for implanted ports, as well as pain on injection of morphine, pump pocket seromas, CSF leaks, CSF hygromas, and postspinal headache. The use of injection ports appears to reduce the rate of complications associated with percutaneously inserted epidural catheters. A retrospective comparison of catheters with or without associated injection ports indicated that those attached to ports became dislodged much less frequently and were associated with half the infection rate per 1000 patient-days. Port removal rates for infection were similar to removal rates of ports used for vascular access (10%). Because the seromas act as growth media for bacterial contamination, they should be monitored carefully. The management of hygromas and postspinal headache is reviewed elsewhere. Ports and pumps can also erode through the skin. Detailed access and management procedures are available for epidural ports and implanted pumps and for monitoring patients receiving opioids through them.

Ommaya Reservoir

The Ommaya reservoir device was first described in 1963 by Ommaya, and with minimal changes, it is still used for access to the spinal fluid within the cerebral ventricle. The reservoir is used to remove CSF for culture, cytology, or measurement of drug levels; to drain cysts in craniopharyngiomas and astrocytomas; to administer antibiotics or antifungal agents; to administer intraventricular chemotherapy to treat leukemic or carcinomatous meningitis; to administer interferon or lymphokine-activated killer cells directly into a tumor; and to administer opioid pain medications.

The device consists of a dome- or mushroom-shaped capsule with a top made of a self-sealing silicone elastomer that can be punctured numerous times without leaking. The flat base of the capsule, by contrast, is composed of firm polypropylene and is not easily punctured. An outlet arm connected to a ventricular catheter is attached at the base, laterally or in the center, extending downward. Capsules range from 12 mm in diameter (for babies) to 30 mm. Those commonly used for adults have an internal volume capacity of 1.45 to 2.4 mL.

Insertion

The Ommaya reservoir is placed subcutaneously by a neurosurgeon. Before insertion, CT is generally required to evaluate ventricular size and placement. Presoaking the device in bacitracin to prevent subsequent infection has been advocated. For placement, the ventricular catheter is passed through a burr hole into the frontal horn of the right lateral ventricle or, if necessary, into that of the left lateral ventricle or the ventricle body. The catheter end is connected to the base or side arm of the capsule, which then is fitted into the burr hole or a subgaleal pocket. The Silastic skirt of the reservoir may be sutured to the periosteum. A postoperative CT scan is suggested to verify the catheter tip position. Stereotactic techniques are used when the ventricle is small or misplaced.

Accessing the Device

The Ommaya reservoir can be used immediately postoperatively for sampling CSF or for injection of drugs. Usually, however, it is not accessed until the third postoperative day. The thoroughly cleaned, gently shaved scalp is prepared with three iodine scrubs, and with the use of a sterile technique, the reservoir is accessed obliquely with a 23- or 25-gauge butterfly needle inserted with the bevel downward. The CSF can be directly aspirated, or antibiotics or chemotherapeutic agents can be administered through a second syringe attached to the butterfly needle. After removal of the needle, the injected medication can be gently pumped into the spinal fluid by emptying the capsule using repeated pressure, but to allow CSF to refill the reservoir, the clinician should avoid steadily compressing the device. After the incision has healed and the stitches have been removed, no special local care or flushing is required. The device can remain in place for months or years. More detailed accessing and management guidelines are available.[2]

Complications

Infection

In general, the Ommaya reservoir has proved very safe, with a complication rate of 9% to 20%, although higher rates were reportedin the past.[20] The most common complication is infection, which occurs in about 1% to 15% of patients, especially those who have undergone radiation therapy or who required a second surgical procedure for revision of the catheter. Most infections have been caused by *S. epidermidis,* but infections from numerous other gram-positive and gram-negative bacteria and fungal organisms have been documented. In general, the device is not removed, and patients are treated as though they had meningitis. For infections with *S. epidermidis,* vancomycin is given intravenously or, in refractory cases, instilled into the reservoir. Removal of the reservoir is sometimes required.

Miscellaneous Complications

Neurologic complications are rare when the catheter is placed into the nondominant ventricle, but a variety of other complications, which occur infrequently, have been reported. These include intraventricular hemorrhage or subdural hematoma shortly after catheter placement; leakage of CSF around the catheter, primarily in patients with increased intracranial pressure, which caused backflow of fluid along the catheter and produced a subgaleal collection; reservoir leaks after repeated use; occlusion by cellular debris or, when a catheter is placed directly into a tumor, by very proteinaceous tumor fluid; obstruction by lodging of the catheter in brain tissue or abutment against a ventricle wall; seizures immediately after injection of medications; white matter disease (leukoencephalopathy or brain necrosis), most often due to methotrexate injection through the Ommaya device, although found with systemic administration of methotrexate as well; and tumor growth around the cannula. In one

case, the catheter may have permitted the spread of Burkitt lymphoma cells from the meninges into the cerebral tissue, where the tumor was found.

CHAPTER 90

NUTRITIONAL ISSUES IN PATIENTS WITH HEMATOLOGIC MALIGNANCIES

Regina S. Cunningham

Nutritional status plays a critical role in predicting risk for the development of human malignancies, affecting responses to therapeutic interventions, and influencing the outcome of disease. Ongoing research has demonstrated that diet can significantly influence the development of hematologic malignancies, and in those who are diagnosed, nutritional status has been correlated with overall survival, chemotherapy response rates, toxicity, quality of life, length of stay, functional status, and cost of care outcomes.[1-8] Nutritional alterations can manifest at any point along the cancer trajectory; they may serve as a harbinger of disease, develop during the treatment process, and often accompany advanced disease. Nutritional alterations in patients with hematologic malignancies can develop as a result of tumor–host interactions, a consequence of cancer treatment, or as a result of psychosocial responses to the disease; most often, the etiology is multifactorial.[9]

SCOPE OF THE PROBLEM

Nutritional problems are common in cancer patients and in those who have survived the disease. Both malnutrition and overnutrition are associated with cancer, but the precise incidence or prevalence of these issues is not well documented. It is estimated that as many as 87% of patients experience weight loss or malnutrition during their trajectory of illness, depending on the site and stage of disease.[8] Approximately 20% of cancer patients die as a result of malnutrition or complications of weight loss rather than from the malignancy itself.[10] The specific incidence of nutritional issues within the hematologic malignancies are not well documented. In general, nutritional alterations are less common among patients diagnosed with hematologic malignancies than in those who have solid tumors. Patients with leukemia are at a relatively low risk for weight loss, but 31% to 48% of patients with non-Hodgkin lymphoma experience significant weight loss.[11] Nutritional deficits have also been reported in myeloma patients undergoing bone marrow transplant. In one study, 61% of patients were found to have altered nutritional status before receiving high-dose chemotherapy.[12] Decreases in lean body mass index (LBMI) have been reported in both adults and children who have been treated with allogeneic stem cell transplantation (aSCT). In a longitudinal study of 82 adult patients with primary hematologic malignancies who underwent aSCT, 38% were found to have LBMIs that were lower than pretreatment levels 4 to 6 years after their transplants had been completed.[13] Decline in body mass index (BMI) over time has also been reported in survivors of pediatric hematologic malignancies after aSCT.[14] Weight loss and diminished nutritional status have been documented in patients with chronic graft-versus-host disease (GVHD), although the frequency and severity has not been well characterized. Patients with advanced GVHD frequently become nutritionally depleted with loss of lean body mass and diminished functional status.[15] One study involving a sample of 93 patients with chronic GVHD found that 43% were malnourished (defined as a BMI of 21.9) and 14% severely malnourished (defined as a BMI of <18.5).[16] Patients with myeloproliferative neoplasms (MPNs) can also experience malnutrition as a result of their disease process. The presence of hypercatabolic symptoms, defined as weight loss, profound fatigue, night sweats, and low-grade fever, at the time of diagnosis is an indicator of adverse prognosis in patients who have primary myelofibrosis.[17] Moreover, in patients with MPNs, long-term complications often include progressive constitutional symptoms, cachexia, and weight loss.[18] A recent study documented that male patients experience greater symptomatology and weight loss and that symptom burden in this population is correlated with decreased quality of life.[19]

Diminished nutritional status in patients with hematologic malignancies can be profound and lead to significant weakness and decline in functional status. Nutritional deterioration and weight loss are associated with poorer responses to treatment and survival outcomes, as well as higher complication rates, longer hospitalizations, greater risk of unplanned hospitalization, higher readmission rates, more disability, and higher overall cost of care.[2,20] In a classic study of the prognostic effects of weight loss among subjects participating in Eastern Cooperative Oncology Group protocols, patients with hematologic malignancies who experienced no weight loss had a median survival approximately twice as long as those who experienced weight loss.[8] From a patient perspective, changes in weight often serve as an ostensible sign of illness and can affect patients' sense of well-being and quality of life. This can be exacerbated when patients develop symptoms as a result of their disease or treatment that have the potential to further impede nutritional intake. Oral pain, hoarseness, nausea, vomiting, mucositis, and unclear speech have all been associated with decreased quality of life scores in patients with cancer.[21,22]

Overnutrition has been identified as a risk factor in the development of hematologic malignancies.[4,23] The relationship between increased BMI and risk for developing both acute and chronic myeloid and lymphoid leukemia has been supported in several large cohort studies as well as meta-analyses. Risk for the development of non-Hodgkin lymphoma, B-cell lymphoma, and multiple myeloma has also been correlated with increased BMI.[24] In addition to the potential etiologic association between overnutrition and hematologic malignancies, obesity may have profound effects on interventions used in the treatment of these diseases. Weight can impact the dose and pharmacokinetics of chemotherapeutic agents, as well as adipocyte metabolism and drug distribution. These factors may be especially important in the setting of hematopoietic stem cell transplantation (HSCT).[25]

Overnutrition has also been reported as an outcome of disease in patients diagnosed with hematologic malignancies.[26,27] Many Childhood Cancer Survivor Study participants are at increased risk for obesity. The etiology of their obesity is likely multifactorial and not well understood.[26] In a retrospective cohort of survivors of childhood acute lymphocytic leukemia (ALL), 1765 adult survivors were compared with 2565 adult siblings on a number of anthropometric outcomes. Findings indicated that subjects who had been treated with cranial radiation therapy at doses of 20 Gy or greater were at greater risk for obesity, particularly female patients who were treated at a younger age. Researchers hypothesized that cranial radiation at a young age may affect the developing hypothalamus and result in leptin-receptor insensitivity.[28] Obesity after a cancer diagnosis is associated with adult-onset diabetes mellitus, hypertension, dyslipidemia,

and ultimately cardiovascular disease.[29] Additional research focusing on elucidating the mechanisms for increased weight and preventing obesity in survivors of hematologic malignancies is needed.

ETIOLOGY AND CONTRIBUTING FACTORS

Many factors contribute to nutritional alterations and weight loss in patients with hematologic malignancies. A decrease in oral intake in the setting of increased energy requirements frequently leads to loss of weight. The type and location of tumors may contribute to the development of symptoms that lead to decreased oral intake. Physiologic alterations related to the tumor (e.g., malabsorption or obstruction), tumor–host interactions (anorexia and altered metabolism), and the development of nutrition-impact symptoms associated with cancer treatment (e.g., nausea, vomiting, mucositis, pain, diarrhea) can all contribute to decreased oral intake and the inability to maintain weight. Symptom burden can be profound in patients with hematologic malignancies, especially in those who are receiving complex multimodality therapies.

All types of cancer treatment have the potential to impact nutritional status. The magnitude of this effect depends on the type, dose, intensity, and duration of treatment. Aggressive multimodality therapeutic interventions that include chemotherapy and radiation therapy are frequently used in the setting of hematologic malignancies. Chemotherapy is associated with both direct and indirect effects that have the potential to interfere with nutritional intake. Rapidly dividing cells are most vulnerable to the effects of chemotherapy and radiation. Alterations in the gastrointestinal (GI) tract after these treatments include damage to the mucosal lining of the oral cavity, changes in the length and surface of the intestinal villi, stimulation of neurobiologic pathways controlling nausea and vomiting, and interference with specific metabolic and enzymatic reactions. The extent of radiation-induced nutritional alterations varies according to the anatomic location, dose, and duration of treatment.[30] Surgical interventions may also lead to alterations in nutritional status, although extensive surgical procedures are less common in patients with hematologic malignancies than they are in those with solid tumors.

CANCER- AND TREATMENT-INDUCED ALTERATIONS IN NUTRITIONAL STATUS

Anorexia

Anorexia is defined as loss of desire to eat accompanied by diminished oral intake.[31] Anorexia often accompanies other symptoms that can lead to decreased food intake and are associated with central nervous system regulation of energy intake, such as changes in sense of smell and taste, nausea, vomiting, and early satiety. Approximately 50% of patients newly diagnosed with cancer experience anorexia, and in later stage disease, the prevalence of this symptom approaches 80%.[32] Prolonged anorexia has been reported in recipients of autologous stem cell transplantation (ASCT).[33] Myeloablative conditioning regimens frequently lead to anorexia and poor oral intake. In a prospective study of 147 patients receiving cyclophosphamide, total-body irradiation, and allogeneic stem cell grafts, oral caloric intake was found to be reduced in 92% of subjects. The nadir in oral intake was noted at days 10 to 12 when the median caloric intake was only 3% of basal energy requirements.[34] Anorexia can lead to malnutrition, decreased ability to tolerate treatment, increased toxicity, debilitation, and decreased quality of life.[32]

Anorexia is a complex physiologic phenomenon that is regulated by numerous GI, metabolic, and endocrine mechanisms. Loss of appetite is associated with gastric motor dysfunction[33] as well as the effects of hormones (e.g., leptin, ghrelin), neuropeptides, and cytokines produced by the cancer and the host in response to the disease.[31,35] Cytokines, including tumor necrosis factor-α (TNF-α), interferon-γ (IFN-γ), leukemia inhibitory factor (LIF), interleukin-1 and -6 (IL-1 and -6), and ciliary neurotrophic factor, are thought to play a pivotal role in the stimulation of anorexigenic and orexigenic circuits that regulate intake and body weight.[31]

Loss of appetite may be precipitated by cancer-induced psychologic distress as well. Depression, anxiety, pain or analgesic medication, and situational factors (isolation, dislike of hospital food) may negatively influence food intake. Cancer-related fatigue, the most commonly reported symptom in patients with cancer, has also been associated with diminished food intake. Fatigue often interferes with activities of daily living and may limit the patient's ability to obtain and prepare food. In many patients, anorexia may linger long after cancer treatment has been completed.

Mucositis

Mucositis is a generalized inflammatory response of the mucosal epithelial cells lining the GI tract. The rapidly dividing cells in this area are particularly vulnerable to the effects of treatment with antineoplastic agents. The clinical presentation of mucositis includes painful inflammation, erythema, and ulcerations of the oral mucosa and GI tract.[36,37] The erythematous ulcerative lesions are a consequence of epithelial damage and cell death that is mediated through a complex series of molecular and cellular events associated with chemotherapy or radiation.[38,39] Mucositis usually develops within 5 days of chemotherapy with peak severity in 7 to 10 days.[36,40] Mucositis is commonly reported in patients receiving conventional chemotherapy, and the risk for developing this symptom increases with each subsequent course of therapy.[41] There is substantial variability in the stomatoxicity of chemotherapeutic regimens used to treat hematologic malignancies. In the setting of Hodgkin disease, for example, the incidence of mucositis with the administration of ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) is 3%.[42] Patients with acute myeloid leukemia (AML), who receive anthracycline-based regimens, often develop profound myelosuppression and oral mucositis (10%-15%). More aggressive protocols, such as FLAG (fludarabine, cytarabine, and granulocyte colony-stimulating factor [G-CSF]) induce mucosal damage in 50% of patients[43] and in patients receiving myeloablative chemotherapy regimens in preparation for stem cell transplantation, severe mucosal toxicity occurs in 60% to 100%.[44-46] Conditioning regimens that contain melphalan or total-body irradiation are associated with particularly high rates of oral mucositis.[47] Targeted therapies have also been associated with the development of oral complications that may be independent or additive.[37,48] Imatinib mesylate (Gleevac–Gilvec, Novartis), for example, is a TKI that selectively targets platelet-derived growth factor receptor, C-kit, and the abl-bcr fusion gene. Several case reports of patients developing oral lichenoid reactions presenting as erythematous reticular plaques on oral mucosa with or without ulceration have been reported.[49,50]

Recent surveys have indicated that mucositis is a serious toxicity reported by patients undergoing high-dose chemotherapy or chemoradiation.[51,52] Severe pain almost uniformly accompanies mucositis, a factor that can severely limit oral intake and lead to changes in nutritional status. Mucositis is also associated with increased need for total parenteral nutrition and opioid analgesics, longer hospitalizations, and increased risk for infection.[41,53,54]

Preventing or minimizing mucositis is an important goal in patients with hematologic malignancies receiving high-dose chemotherapy. The Multinational Association for Supportive Care in Cancer recommends the use of keratinocyte growth factor-1 (palifermin) at a dosage of 60 μg/kg per day for 3 days before administration of a conditioning regimen of aSCT and for 3 days posttransplant for the prevention of oral mucositis.[47,55] Strong evidence supports the benefits of palifermin in reducing both the severity and duration of oral mucositis as well as decreasing mouth and throat soreness and improving patient function in the setting of aSCT.[56,57] Cryotherapy to prevent oral mucositis in patients receiving high-dose melphalan as a conditioning agent in HSCT is also recommended.[47]

Early Satiety

Early satiety is defined as the desire to eat associated with the subsequent inability to eat (except for small amounts) because of a sense of fullness.[58] In a recent prospective evaluation of more than 1000 patients with advanced cancer, early satiety was ranked among the 10 most common symptoms experienced by patients.[59] Another investigation of patients with MPNs reported that early satiety was experienced by 53% of patients with essential thrombocytosis, 62% of those with polycythemia vera, and 75% of patients who had myelofibrosis.[18] Early satiety often occurs with other symptoms, including anorexia, taste changes, and weight loss.[60] Early satiety contributes to decreased food intake and has been identified as an independent prognostic variable.[59]

Both central and peripheral pathophysiologic mechanisms as well as physical barriers contribute to the development of early satiety. Central influences can alter smell and taste and lead to food aversions as well as diurnal variations in food intake. Satiety is less prominent during the early hours of the day. Peripheral mechanisms underlying early satiety include gastric dysmotility and accommodation as well as the influence of specific gastric and small bowel hormones. Physical barriers that contribute to the development of early satiety include a lack of gastric accommodation and delayed gastric emptying.[60] In patients with MPNs, for example, early satiety may be related to gastric compression that occurs as a result of the striking hepatosplenomegaly that is frequently associated with extramedullary hematopoiesis.

Chemosensory Alterations in Taste and Smell

Alterations in taste and smell are common in patients with cancer and in those receiving chemotherapy. In an investigation of subjects with advanced cancer, 86% of patients reported some type of chemosensory alteration.[61] In another study of 518 patients receiving ambulatory chemotherapy, 66% of patients reported changes in taste and smell. An additional 8% experienced changes in smell without changes in taste.[62] Although this investigation included patients with mixed cancer diagnoses, olfactory changes have been reported among patients receiving high-dose chemotherapy followed by aSCT. In one study of 50 subjects, 26% reported that they experienced increased sensitivity to odors, and 8% reported decreased sensitivity. Other changes affecting smell were reported by 24% of subjects.[63] Altered taste and smell sensors, with diminution of taste and olfactory cues, change the normal references that are important to appetite and intake. Increases in the recognition thresholds for sweet, sour, and salty as well as decreases in the recognition levels for bitter are seen frequently in patients receiving cancer treatment. Such changes can lead to food aversions, which in turn can decrease food intake and lead to malnutrition. Psychosocial factors may also contribute to food aversions. Pleasurable and social aspects of eating can be negatively influenced by alterations in taste or smell, leading to a reduced desire to eat and diminished intake.

Taste alterations are defined as changes in the usual patterns of taste perception that are unique to the individual experiencing the changes.[64] Taste alterations may result in reduced interest in food and decreased oral intake, nutritional compromise, and weight loss. Moreover, because one of the basic qualities of taste is desirable flavor associated with pleasure, changes in taste have also been associated with decrease in quality of life.[63] Although taste alterations are common in patients with cancer, they may be overlooked because of more pressing consequences of disease and treatment. As such, data on incidence, prevalence, and the impact of these symptoms on nutritional status are limited. Changes in taste and smell may be related to effects of tumors, cancer-induced deficiencies of vitamins and minerals, selected chemotherapeutic agents, or the action of cytokines. The perception of taste may be distorted (dysgeusia), which will often be described by patients as rancid, bitter, salty, or metallic. Taste alterations can also include enhanced (hypergeusia), diminished (hypogeusia), or completely absent (ageusia). Dysosmia, or distorted perception of smell, is categorized according to whether it is preceded by something in the environment (parosmia) or happens spontaneously (phantosmia). Dysosmia is often unpleasant and is frequently described by patients as rancid.[61,65]

Cancer Cachexia

Cachexia is a multifactorial syndrome characterized by progressive weight loss, anorexia, asthenia, skeletal muscle and adipose tissue loss, and dysregulated metabolic changes with increased basal energy expenditure that is resistant to conventional nutritional support interventions.[66,67] Cachexia is one of the most profound alterations in nutrition that is observed in patients with cancer, and it is associated with declining performance status, decreased quality of life, and shortened survival. Weight loss in cachexia is caused by depletion of adipose tissue and skeletal muscle mass as well as changes in glucose metabolism.

Body mass is controlled by the balance of energy intake and expenditure. Glucose is the most essential substrate of the human body and is required to support all critical organ functions. In the setting of cachexia, the intake of glucose can be severely compromised by anorexia and other symptoms impacting nutrition. This is exacerbated by cancer-induced changes in glucose metabolism that lead to inefficient production in the setting of increased need.[68] Most cancer cells use glycolysis as the principal method to generate adenosine triphosphate. The increased glucose uptake in tumors is the basis of the [^{18}F] fluorodeoxyglucose positron emission tomography (FDG-PRT) tumor diagnostic method.[69] The reasons for this phenomenon is not clear; it has been hypothesized that it is related to dysfunctional mitochondria, which prevent their use of the tricarboxylic acid cycle, preventing total combustion of pyruvic acid.[70] The result is the conversion of glucose to lactic acid, an extremely inefficient process. Tumor growth requires approximately 40 times more glucose than if it was fully oxidized through the tricarboxylic cycle. In addition, lactate passes from the tumor to the liver, where it is resynthesized into glucose.[71] This may account for an additional loss of energy in cancer patients of about 300 kcal/day.[72]

Changes in protein metabolism and depletion of muscle mass are also features of cancer cachexia. Depletion of skeletal muscle is the result of an imbalance between the rate of protein synthesis and degradation. There is an overall increase in muscle protein catabolism leading to a net loss of muscle mass. Proteolysis-inducing factor (PIF) is a glycoprotein secreted by cachexia-inducing tumors that has been shown to inhibit protein synthesis and stimulate protein degradation directly. PIF is also involved in hepatic gene expression, which can influence the production of cytokines that are implicated in the cachectic process.[73,74] Cachexia is also associated with significant reduction in adipose tissue. This is driven by lipid-mobilizing factor and other tumor–host factors that have direct lipolytic effects.[67] These changes lead to decreased body fat, which is lost more readily than lean tissue.[71]

The pathophysiologic mechanisms underlying cachexia have not been fully elucidated. It is hypothesized that the syndrome is the result of highly complex cell signaling between the tumor and host. Cytokines play an important role in mediating many of the metabolic changes seen in cancer cachexia. Proinflammatory cytokines can modulate gastric motility and emptying either directly through the GI tract or by altering signals that regulate satiety. TNF-α, or cachectin, leads to decreased food intake and wasting. IFN-γ is also produced and has biologic functions that overlap with TNF. Ciliary neurotrophic factor is expressed in skeletal muscle and has been shown to induce cachectic effects and produce acute-phase proteins. LIF and transforming growth factor-β are also produced and are hypothesized to play a role in the development of cachexia.[75-77] Elucidating the molecular mechanisms underlying the development of cachexia is an area of active research. This knowledge is essential to guide the development of rational therapeutics to manage cachexia in the future.

Energy Balance in Cancer

Energy balance is the difference between dietary energy intake and expenditure through physical activity and resting metabolism. It is the result of the complex interaction of diet, physical activity, and genetics. Changes in energy intake are common in patients with hematologic malignancies; they may have increased, normal, or decreased energy expenditure. Increased energy expenditure may result from tumor–host interactions that facilitate changes in metabolism and appetite. Heightened cytokine activity, inefficient metabolic cycles, protein destruction, acute-phase reactions, and inappropriate energy production in response to decreased intake can all lead to increased energy requirements. It is estimated that energy requirements in aSCT recipients may reach 130% to 150% of predicted basal energy expenditure.[78] Patients may also experience infection and fever, which can further increase energy demands. In response to these demands, nutritional needs increase as the body tries to repair damage. Cancer treatments may lead to both increases and decreases in energy expenditure. Many cancer treatments are associated with the development of symptoms that impact oral intake and influence functional status. Most chemotherapeutic agents stimulate the emetic pathways, leading to nausea and vomiting. Specific drugs, such as doxorubicin and cyclophosphamide, are associated with changes in taste and smell perception. Radiation can also damage taste and olfactory receptors. In addition, radiation can damage the salivary glands, causing xerostomia. The lack of saliva creates an extremely dry mouth and makes food consumption very challenging. Patients who develop GVHD can experience profound diarrhea, leading to changes in fluid status and electrolyte balance. All of these changes can lead to decreased energy intake and weight loss. Decreased energy expenditure can also be seen in patients with hematologic malignancies. This may occur as a result of deconditioning from lengthy hospitalizations, decreased physical activity, or changes in metabolic rate resulting from loss of muscle.

Specialized Nutritional Issues in Hematopoietic Cell Transplantation

Hematopoietic stem cell transplantation is a therapeutic intervention used in the management of many hematologic malignancies. HSCT describes a diverse group of interventions, the outcomes of which depend on the type of transplant (autologous, related or unrelated allogeneic), preparative regimen, degree of histocompatibility, stem cell source (bone marrow, peripheral blood, or cord blood), age, type and stage of disease, previous therapy, and nutritional status. One of the major adverse effects of HSCT is malnutrition.[66,79,80] HSCT involves the use of high-dose chemotherapy with or without radiation to eradicate tumor; hematologic rescue is then provided with previously harvested cells. Many of the preparative chemotherapeutic regimens used in HSCT are extremely intense and are associated with severe mucositis, enteritis, painful oral ulcerations, nausea, vomiting, and profound diarrhea. All of these symptoms can lead to diminished oral intake, significant weight loss, and malnutrition. Disruption of the mucosal barrier predisposes patients to the development of infection during the period of neutropenia, which may last for as long as 6 weeks.[66] The development of GVHD can exacerbate these symptoms and complicate the clinical picture with the addition of hepatic and renal insufficiency. Underweight transplant recipients have a greater risk of death in the early posttransplant period as well as greater nonrelapse mortality.[80] Conversely, a shorter time to engraftment and lower probability of developing infection are associated with being well nourished.

Nutritional deficits that develop in transplant patients linger long after completion of the transplant, with as many as 50% of patients not returning to their pretransplant weight at 1 year.[66] According to the American Society for Parenteral and Enteral Nutrition (ASPEN) Clinical Guidelines, all patients undergoing HSCT with myeloablative preparatory regimens are at nutritional risk and should undergo nutritional screening to identify those who require a more extensive nutritional assessment and development of a nutritional care plan. These proactive steps will assist in the early identification of patients who are at risk of developing nutritional alterations and facilitate early intervention for these issues.

NUTRITIONAL SCREENING AND ASSESSMENT

Early intervention is the cornerstone of effective management of nutritional issues in patients with hematologic malignancies. Nutritional screening is an essential preliminary step in the development of a successful nutritional plan. The major goals of nutritional screening are to proactively identify patients who are at risk for malnutrition, prevent or treat malnutrition early, and modify treatment plans as necessary. Both The Joint Commission (TJC) and the ASPEN endorse the identification of patients with actual or potential nutritional issues through a systematic screening process. TJC requires the identification of patients who are at nutritional risk within 24 hours of admission to a hospital, within 14 days of admission to a long-term care facility, and within an organizationally specified time period in the ambulatory and home care settings.[65] ASPEN has developed guidelines that recommend that all patients undergo nutritional screening as a component of their initial assessment.[81]

Nutritional screening tools typically include both objective and subjective data that can be obtained quickly and easily in a busy clinical setting. Objective data should at a minimum include height, weight, weight change, primary diagnosis, and the presence of comorbidities. Subjective components include patient-reported information about symptoms, changes in dietary intake, and activity levels.

The need to efficiently screen for nutritional issues has led to the development of a number of clinical tools. Screening tools should be easy to use, valid, reliable, cost effective, and sensitive. The Patient-Generated Subjective Global Assessment (PG-SGA) has been identified by the Oncology Nutrition Practice Group and the Academy of Nutrition and Dietetics as the standard for nutritional screening in oncology patients. The PG-SGA was adapted from the Subjective Global Assessment specifically for use in the cancer population by Ottery.[82] The form (Fig. 90-1) uses a simple check box format to obtain information from both the patient and the clinician. Each of the patient's subjective responses is scored from 0 (least) to 4 (most) depending on nutritional impact. This score is combined with objective data collected by the clinician, and a total score is calculated. The overall PG-SGA score indicates if a patient is well nourished, suspected of being malnourished, or severely malnourished. An algorithm (Fig. 90-2) outlining nutritional interventions for each of these categories has been developed.

The PG-SGA has demonstrated good construct validity and interrater reliability.[83] In a sample of 61 consecutive patients with hematologic malignancies newly admitted to a transplant program, patients completed a battery of standardized supportive care measures, including the PG-SGA. A total of 61% of patients experienced nutritional deficits, indicating the need for attention to nutritional difficulties, before the administration of high-dose therapy and transplantation.[12] In another investigation, the PG-SGA was used to assess nutritional risk among hospitalized cancer patients (49% of whom had a diagnosis of lymphoma). In this setting, the instrument demonstrated 98% sensitivity and 82% specificity of predicting patients who were well nourished, moderately malnourished, or severely malnourished.[84] Nutritional status is often used as a proxy for well being. The PG-SGA has also been used as a predictor of length of stay in patients with hematologic malignancies. In a sample of patients with multiple myeloma, non-Hodgkin lymphoma, B-cell lymphoma, chronic lymphocytic leukemia, and AML who were admitted to the hospital for HSCT, those who were identified as being malnourished at baseline required longer hospitalizations.[85]

Other nutritional screening tools have been effectively used in the oncology setting. The Mini Nutritional Assessment[86] is a screening tool that is completed by clinicians that includes information on weight history, food intake, activity, psychosocial stress, and anthropometric measures. The Malnutrition Screening Tool[87] elicits similar

Scored Patient-Generated Subjective Global Assessment (PG-SGA)

Patient ID Information

History (Boxes 1-4 are designed to be completed by the patient.)

1. Weight *(See Worksheet 1)*

In summary of my current and recent weight:

I currently weigh about _____ pounds
I am about _____ feet _____ tall

One month ago I weighed about _____ pounds
Six months ago I weighed about _____ pounds

During the past two weeks my weight has:
☐ decreased (1) ☐ not changed (0) ☐ increased (0)

Box 1

2. Food Intake: As compared to my normal intake, I would rate my food intake during the past month as:

☐ unchanged (0)
☐ more than usual (0)
☐ less than usual (1)

I am now taking:

☐ *normal food* but less than normal amount (1)
☐ little solid food (2)
☐ only liquids (3)
☐ only nutritonal supplements (3)
☐ very little of anything (4)
☐ only tube feedings or only nutrition by vein (0)

Box 2

3. Symptoms: I have had the following problems that have kept me from eating enough during the past two weeks (check all that apply):

☐ no problems eating (0)
☐ no appetite, just did not feel like eating (3)
☐ nausea (1)
☐ constipation (1)
☐ mouth sores (2)
☐ things taste funny or have no taste (1)
☐ problems swallowing (2)
☐ pain; where? (3)_____
☐ other** (1) _____
☐ vomiting (3)
☐ diarrhea (3)
☐ dry mouth (1)
☐ smells bother me (1)
☐ feel full quickly (1)
☐ fatigue (1)

** Examples: depression, money, or dental problems

Box 3

4. Activities and Function: Over the past month, I would generally rate my activity as:

☐ normal with no limitations (0)
☐ not my normal self, but able to be up and about with fairly normal activities (1)
☐ not feeling up to most things, but in bed or chair less than half the day (2)
☐ able to do little activity and spend most of the day in bed or chair (3)
☐ pretty much bedridden, rarely out of bed (3)

Box 4

Additive Score of the Boxes 1-4 ☐ **A**

Scored Patient-Generated Subjective Global Assessment (PG-SGA)

Worksheet 1 - Scoring Weight (Wt) Loss

To determine score, use 1 month weight data if available. Use 6 month data only if there is no 1 month weight data. Use points below to score weight change and add one extra point if patient has lost weight during the past 2 months

Wt loss in 1 month	Points	Wt loss in 6 months
10% or greater	4	20% or greater
5-9.9%	3	10-19.9%
3-4.9%	2	6-9.9%
2-2.9%	1	2-5.9%
0-1.9%	0	0-1.9%

Numerical score from Worksheet 1 ☐

Additive Score of the Boxes 1-4 (See Side 1) ☐ A

5. Worksheet 2 - Disease and its relation to nutritional requirements

All relevant diagnoses (specify) _____

One point each:

☐ Cancer ☐ AIDS ☐ Pulmonary or cardiac cachexia ☐ Presence of decubitus, open wound, or fistula
☐ Presence of trauma ☐ Age greater than 65 years ☐ Chronic renal insufficiency

Numerical score from Worksheet 2 ☐ B

6. Work Sheet 3 - Metabolic Demand

Score for metabolic stress is determined by a number of variables known to increase protein & calorie needs. The score is additive so that a patient who has a fever of >102 degrees (3 points) and is on 10 mg of prednisone chronically (2 points) would have an additive score for this section of 5 points.

Stress	none (0)	low (1)	moderate (2)	high (3)
Fever	no fever	>99 and <101	≥101 and <102	>102
Fever duration	no fever	<72 hrs	72 hrs	>72 hrs
Corticosteroids	no corticosteroids	low dose (<10 mg prednisone equivalents/day)	moderate dose (≥10 and <30 mg prednisone equivalents/day)	high dose steroid (≥30 mg prednisone equivalents/day)

Numerical score from Worksheet 3 ☐ C

7. Worksheet 4 - Physical Exam

Physical exam includes a subjective evaluation of 3 aspects of body composition: fat, muscle, & fluid status. Since this is subjective, each aspect of the exam is rated for degree of deficit. Muscle deficit impacts point score more than fat deficit. Definition of categories: 0 = no deficit, 1+ = mild deficit, 2+ = moderate 3+ = severe

Muscle Status:				
temples (temporalis muscle)	0	1+	2+	3+
clavicles (pectoralis & deltoids)	0	1+	2+	3+
shoulders (deltoids)	0	1+	2+	3+
interosseous muscles	0	1+	2+	3+
Scapula (latissimus dorsi, trapezius, deltoids)	0	1+	2+	3+
thigh (quadriceps)	0	1+	2+	3+
calf (gastrocnemius)	0	1+	2+	3+
Global muscle status rating	**0**	**1+**	**2+**	**3+**
Fat Stores:				
orbital fat pads	0	1+	2+	3+
triceps skin fold	0	1+	2+	3+
fat overlying lower ribs	0	1+	2+	3+
Global fat deficit rating	**0**	**1+**	**2+**	**3+**

Fluid Status:				
ankle edema	0	1+	2+	3+
sacral edema	0	1+	2+	3+
ascites	0	1+	2+	3+
Global fluid status rating	**0**	**1+**	**2+**	**3+**

Numerical score from Worksheet 4 ☐ D

Total PG-SGA score ☐
(Total numerical score of A+B+C+D above)
(See triage recommendations below)
Global PG-SGA rating (A, B, or C) = ☐

Clinician Signature _____ RD RN PA MD DO Other ___ Date _____

Worksheet 5 - PG-SGA Global Assessment Categories

	Stage A	Stage B	Stage C
Category	Well nourished	Moderately malnourished	Severely malnourished
Weight	No wt loss **OR** Recent wt gain	≤5% wt loss in 1 month (or 10% in 6 mos) **OR** Progressive wt loss	>5% wt loss in 1 month (or >10% in 6 mos) **OR** Progressive wt loss
Nutrient intake	No deficit **OR** Significant recent improvement	Definite decrease in intake	Severe deficit in intake
Nutrition Impact Symptoms	None **OR** Significant recent improvement allowing adequate intake	Present of nutrition impact symptoms (PG-SGA Box 3)	Present of nutrition impact symptoms (PG-SGA Box 3)
Functioning	No deficit **OR** Recent improvement	Moderate functional deficit **OR** Recent deterioration	Severe functional deficit **OR** recent significant deterioration
Physical Exam	No deficit **OR** Chronic deficint but recent improvement	Evidence of mild to moderate loss of muscle mass / SQ fat / muscle tone on palpation	Obvious signs of malnutrition (e.g., severe loss muscle, SQ tissue, possible edema)

Nutritional Triage Recommendations: Additive score is used to define specific nutritional interventions including patient & family education, symptom management including pharmacologic intervention, and appropriate nutrient intervention (food, nutritional supplements, enteral, or parenteral triage).
First line nutrition intervention includes optimal symptom management.

Triage based on PG-SGA point score

0-1	No intervention required at this time. Re-assessment on routine and regular basis during treatment.
2-3	Patient & family education by dietitian, nurse, or other clinician with pharmacologic intervention as indicated by symptom survey (Box 3) and lab values as appropriate.
4-8	Requires intervention by dietitian, in conjunction with nurse or physician as indicated by symptoms (Box 3).
≥9	Indicates a critical need for improved symptom management and/or nutrient intervention options.

Figure 90-1, cont'd PATIENT-GENERATED SUBJECTIVE GLOBAL ASSESSMENT. *(From Ottery FD: Patient-generated subjective global assessment. In McCallum PD, Polisena CG, eds:* The clinical guide to oncology nutrition, *Chicago, 2000, The American Dietetic Association, p 11.)*

Worksheets for PG-SGA Scoring

© FD Ottery, 2001

Boxes 1-4 of the PG-SGA are designed to be completed by the patient. The PG-SGA numerical score is determined using 1) the parenthetical points noted in boxes 1-4 and 2) the worksheets below for items not marked with parenthetical points. Scores for boxes 1 and 3 are additive within each box and scores for boxes 2 and 4 are based on the highest scored item checked off by the patient.

Worksheet 1 - Scoring Weight (Wt) Loss

To determine score, use 1 month weight data if available. Use 6 month data only if there is no 1 month weight data. Use points below to score weight change and add one extra point if patient has lost weight during the past 2 weeks. Enter total point score in Box 1 of the PG-SGA.

Wt loss in 1 month	Points	Wt loss in 6 months
10% or greater	4	20% or greater
5-9.9%	3	10-19.9%
3-4.9%	2	6-9.9%
2-2.9%	1	2-5.9%
0-1.9%	0	0-1.9%

Score for Worksheet 1 = ☐
Record in Box A

Worksheet 2 - Scoring Criteria for Condition

Score is derived by adding 1 point for each of the conditions listed below that pertain to the patient.

Category	Points
Cancer	1
AIDS	1
Pulmonary or cardiac cachexia	1
Presence of decubitus, open wound, or fistula	1
Presence of trauma	1
Age greater than 65 years	1

Score for Worksheet 2 = ☐
Record in Box B

Worksheet 3 - Scoring Metabolic Stress

Score for metabolic stress is determined by a number of variables known to increase protein & calorie needs. The score is additive so that a patient who has a fever of >102 degrees (3 points) and is on 10 mg of prednisone chronically (2 points) would have an additive score for this section of 5 points.

Stress	none (0)	low (1)	moderate (2)	high (3)
Fever	no fever	>99 and <101	≥101 and <102	≥102
Fever duration	no fever	<72 hrs	72 hrs	>72 hrs
Corticosteroids	no corticosteroids	low dose (<10 mg prednisone equivalents/day)	moderate dose (≥10 and <30 mg prednisone equivalents/day)	high dose steroids (≥30 mg prednisone equivalents/day)

Score for Worksheet 3 = ☐
Record in Box C

Worksheet 4 - Physical Examination

Physical exam includes a subjective evaluation of 3 aspects of body composition: fat, muscle, & fluid status. Since this is subjective, each aspect of the exam is rated for degree of deficit. Muscle deficit impacts point score more than fat deficit. Definition of categories: 0 = no deficit, 1+ = mild deficit, 2+ = moderate deficit, 3+ = severe deficit. Rating of deficit in these categories are *not* additive but are used to clinically assess the degree of deficit (or presence of excess fluid).

Fat Stores:				
orbital fat pads	0	1+	2+	3+
triceps skin fold	0	1+	2+	3+
fat overlying lower ribs	0	1+	2+	3+
Global fat deficit rating	**0**	**1+**	**2+**	**3+**
Muscle Status:				
temples (temporalis muscle)	0	1+	2+	3+
clavicles (pectoralis & deltoids)	0	1+	2+	3+
shoulders (deltoids)	0	1+	2+	3+
interosseous muscles	0	1+	2+	3+
scapula (latissimus dorsi, trapezius, deltoids)	0	1+	2+	3+
thigh (quadriceps)	0	1+	2+	3+
calf (gastrocnemius)	0	1+	2+	3+
Global muscle status rating	**0**	**1+**	**2+**	**3+**

Fluid Status:				
ankle edema	0	1+	2+	3+
sacral edema	0	1+	2+	3+
ascites	0	1+	2+	3+
Global fluid status rating	**0**	**1+**	**2+**	**3+**

Point score for the physical exam is determined by the overall subjective rating of total body deficit.

No deficit	score = 0 points
Mild deficit	score = 1 point
Moderate deficit	score = 2 points
Severe deficit	score = 3 points

Score for Worksheet 4 = ☐
Record in Box D

Worksheet 5 - PG-SGA Global Assessment Categories

	Stage A	Stage B	Stage C
Category	Well-nourished	Moderately malnourished or suspected malnutrition	Severely malnourished
Weight	No wt loss **OR** Recent non-fluid wt gain	~5% wt loss within 1 month (or 10% in 6 months) **OR** No wt stabilization or wt gain (i.e., continued wt loss)	>5% wt loss in 1 month (or >10% in 6 months) **OR** No wt stabilization or wt gain (i.e., continued wt loss)
Nutrient Intake	No deficit **OR** Significant recent improvement	Definite decrease in intake	Severe deficit in intake
Nutrition Impact Symptoms	None **OR** Significant recent improvement allowing adequate intake	Presence of nutrition impact symptoms (Box 3 of PG-SGA)	Presence of nutrition impact symptoms (Box 3 of PG-SGA)
Functioning	No deficit **OR** Significant recent improvement	Moderate functional deficit **OR** Recent deterioration	Severe functional deficit **OR** Recent significant deterioration
Physical Exam	No deficit **OR** Chronic deficit but with recent clinical improvement	Evidence of mild to moderate loss of SQ fat &/or muscle mass &/or muscle tone on palpation	Obvious signs of malnutrition (e.g., severe loss of SQ tissues, possible edema)

Global PG-SGA rating (A, B, or C) = ☐

information and can be completed by medical, nursing, or administrative personnel. Both instruments have established validity and reliability in ambulatory cancer settings.

Nutrition Assessment

Patients meeting screening risk criteria are candidates for nutritional assessment. This is a more comprehensive and detailed evaluation that includes a medical and dietary history, anthropometric measurements, body composition analysis, a review of findings from a nutritionally focused physical examination, specific laboratory data, and assessment for symptoms that have the potential to impact nutritional intake.[88] The purpose of nutrition assessment is to gather data to plan for nutrition interventions. Optimally, trained dietary specialists are responsible for performing comprehensive nutritional assessment, planning nutritional interventions, and systematic reassessment of nutritional status. In practice settings where there is not access to registered dietitians, experienced nurses may perform nutritional assessments.

Anthropometrics

Anthropometrics refers to measurement of the human body in terms of dimensions, proportions, and ratios. Anthropometrics commonly

Table 90-1 Common Terminology Criteria for Adverse Events Version 4.02 Grading for Weight Loss

Adverse Event	1	2	3	4	5
Weight loss definition: A finding characterized by a decrease in overall body weight	5% to <10% from baseline; intervention not indicated	10% to <20% from baseline; nutrition support indicated	≥20% from baseline; tube feeding or TPN indicated	—	—

TPN, Total parenteral nutrition.

Table 90-2 Categories of Body Mass Index

Category	Body Mass Index
Underweight	<18.5
Normal Weight	18.5-24.9
Overweight	25-29.9
Obesity	≥30

Source: National Heart, Blood, and Lung Institute, 2012. http://www.nhlbisupport.com/bmi/.

includes weight, height, and skin-fold thickness; these variables are easy to assess in busy clinical practice settings, are noninvasive, and can be accomplished with minimal cost. Weight and height are the most common forms of serial anthropometric measurement performed in clinical practice settings. The measurement of height and weight in the oncology setting is especially critical because dosing for many therapeutic interventions is based on body surface area. It is essential that height and weight be measured longitudinally from a reliable baseline and that the instruments used for measurement are accurate and precise. Longitudinal measurement provides the temporal context to assess weight change in an individual patient; the time period over which weight change occurs is critical. An involuntary loss of 10% or more of body weight within a 6-month period or 5% or more over 1 month is defined as severe weight loss and is associated with poorer outcomes.[89] Changes in performance status have been associated with a 2.5-kg weight loss over a 6- to 8-week period.[67] The Common Terminology Criteria for Adverse Event (CTCAE) reporting for weight loss is shown in Table 90-1. In clinical practice, lower grades of toxicity are often deemed tolerable. The CTCAE indicates that intervention is not indicated for patients experiencing a weight loss of 5% to 10% or less of body weight (grade 1).[90] Moreover, no time frame is identified in this toxicity assessment. Early intervention is the cornerstone to effective management of nutritional issues in patients with hematologic malignancies. As such, the criteria outlined in Table 90-1 facilitate reactive rather than proactive interventions for patients experiencing weight loss.[89]

Instruments used in anthropometric measurement should be recalibrated and checked for accuracy and precision by the manufacturer or the organization's biomedical engineering group at least every 6 months. Clinical practices should develop clear procedures for the measurement of height and weight so that personnel accountable for these activities are able to obtain this information in an accurate and consistent manner. Patients should be instructed to remove overcoats and shoes as well as heavy objects from their pockets before their weight is assessed. Some patients may not be able to be weighed in a standing position. Chair scales, bed scales, and scales that allow measurement of weight while in wheelchairs should be considered in these situations. Height should be measured using a stadiometer with the patient standing with the feet flat on the floor or platform. Anthropometry often includes calculation of BMI, which is a measure of fat based on height and weight. BMI provides information on whether a patient's weight is within a healthy range (Table 90-2) but does not provide any information on body composition.

Body Composition Analysis

Body composition analysis reflects nutritional intake, loss, and need over time. Unlike assessment of height, weight, and BMI, body composition analysis provides measurement of tissue loss by analyzing two major body compartments, fat-free (or lean body) mass and fat mass. Decreases in fat-free mass are associated with impairments in overall health, function, and quality of life.[91] Methods of assessing body composition include bioelectrical impedance analysis (BIA), dual-energy x-ray absorptiometry (DEXA), and computed tomography (CT). BIA is based on the capacity of hydrated tissues to conduct electrical energy and measures impedance or opposition to the flow of an electrical current through body fluids contained mainly in lean and fat tissue. Impedance is proportional to body water volume. BIA is valid, easy to use, and noninvasive. There may be some inaccuracies in patients who have fluid losses, dehydration, or fluid retention, and for these reasons, it is not an optimal strategy in the cancer population. DEXA is a highly accurate and reproducible method of assessing body composition; it is the reference method for assessment in clinical research settings. DEXA provides noninvasive direct measurement of three components of body composition: fat mass, fat-free mass, and bone mineral mass. Although DEXA is frequently used in cancer to assess bone mineral density, it is not commonly used to assess other aspects of body composition longitudinally. Accessibility, operator skill, cost, and radiation exposure are factors contributing to its limited use in this setting. CT provides assessment of fat-free mass through regional analysis of the third vertebra, which strongly predicts whole body fat and fat-free mass. Because CT scanning is used commonly in cancer patient diagnosis and follow-up, this approach has practical benefits because it can be integrated with routine care. Specific software is required to perform these assessments.[91]

Nutrition Biomarkers

Although there is no gold standard test to assess nutrition status, selected laboratory values are often included as part of a comprehensive nutritional assessment. Many of these values are readily available because they are being collected as part of routine care. Circulating proteins, including albumin, prealbumin, transferrin, and retinol-binding protein, are often used as indicators of nutritional status. C-reactive protein, total lymphocyte count, and serum total cholesterol are also common. Low serum albumin or depressed total lymphocyte counts may be early indicators of protein-energy deficiencies; however, because these laboratory tests are influenced by many other variables, they lack sensitivity and should be used along with other variables in making decisions about patients. The usefulness of serum albumin levels as an indicator of nutritional status, for example, is limited by that fact that it can be influenced by hydration status or the presence of ascites. Serum albumin is also a negative acute-phase reactant, meaning that it is decreased in the presence of inflammation, which occurs in many hematologic malignancies as well as other types of cancer. Some laboratory tests may be normal even when deficits are present. Zinc deficiency, for example, is relatively common, but because zinc is primarily stored in muscle and liver tissues with only a small percentage in the serum, zinc levels may appear normal when stores are actually low.[92] Other levels can be influenced by recent

dietary intake or supplements. Serum iron levels, for example, may be elevated by recent food intake, and vitamin C supplementation may lower serum B_{12} levels.

The use of biochemical indices for the assessment of nutritional status in patients with hematologic malignancies undergoing both aSCT and ASCT. aSCT has been investigated. Findings indicated that biochemical indices were not sufficiently reliable in this population of patients because levels were markedly affected by the acute-phase response (measured with acute-phase protein levels) secondary to infections. Prealbumin levels, measured 8 days after completion of the conditioning regimen were, however, helpful about making decisions to start parenteral nutrition (PN) support.[93]

Nutrition Support Strategies

The goals of nutrition support therapy are to ensure adequate intake of calories and protein, minimize symptoms impeding nutritional status, maintain weight, or reverse weight loss, preserve lean body mass, and optimize function and quality of life.[94] Interventions prescribed to support nutrition should be based on the results of nutritional assessment. In addition, the presence of a functional GI tract is an essential consideration in determining a nutritional care plan. Moreover, the patient's ethnicity, culture, preferences, performance status, quality of life, and prognosis, as well as cost effectiveness, should also be taken into account. Interventions may include dietary education and counseling, oral supplementation, nutritional supplements delivered directly into the GI tract, PN, the use of orexigenic or other pharmacologic agents, or some combination of these strategies.

Neutropenic Diets

Neutropenic diets were developed in an effort to decrease infections in neutropenic patients by limiting the introduction of bacteria by food ingestion.[95] The diet evolved from practices used in germ-free protective environments during the 1960s in which patients were isolated and foods sterilized with the goal of preventing colonization by microorganisms.[96] In this environment, patients were able to tolerate higher doses of chemotherapy with less toxicity, including infections.[97] Over the ensuing decades, many of these practices have changed, but the neutropenic diet continues to be part of routine care for patients with low neutrophil counts in many institutions. In a survey of 156 institutions belonging to the Association of Community Cancer Centers, 78% reported the use of restricted diets during periods of neutropenia.[98] Neutropenic diets typically limit consumption of fresh fruits, raw vegetables, aged cheeses, cold meat cuts, fast food, and take-out food. Yogurt and ice cream may also be restricted. These restrictions may limit patient food choices at a time when adequate consumption of calories is critical and contributes to malnutrition. Investigations of the effectiveness of neutropenic diets have not been able to demonstrate appreciable differences between intervention and control groups with respect to the development of febrile neutropenia, neutrophil counts, postchemotherapy filgrastim use, median cycles of chemotherapy,[95] time to major infection, survival,[99] febrile admissions, or gram-negative bacteremia.[100] Without clear evidence, the restrictions concerning diet that are best to recommend are the Food and Drug Administration–-approved food safety guidelines available at http://www.foodsafety.gov.[101]

Dietary Education and Counseling

Individualized early dietary education and counseling is correlated with improved nutritional status and body weight. Dietary counseling includes the prescription of a therapeutic diet that is individualized to meet patient needs. Providing education on specific food choices, such as calorie-dense foods, and the management of symptoms that can impact oral intake can be extremely effective. In a review of evidence investigating the effectiveness of nutritional interventions, a summary of seven studies reporting on the effects of dietary counseling and nutritional supplementation on oral intake found that improved caloric intake was reported in all trials.[102] Clinical trials investigating the effects of dietary counseling specific to patients with hematologic malignancies were not identified in the literature.

The use of oral nutrition supplements is an intervention that is frequently suggested for cancer patients. These supplements may be of benefit in increasing caloric intake in patients who are malnourished, particularly those who have BMIs of less than 20. Moreover, in a Cochrane review, the use of supplements with energy and protein was associated with weight gain, shorter hospitalization, and improved survival.[103]

Specialized Nutritional Support Therapy

Specialized nutrition support includes the use of enteral nutrition (EN) and PN. EN refers to the delivery of nutrition through an enteral feeding device inserted into a functioning GI tract. PN refers to the administration of an admixture of nutrients via the intravenous route. The use of these interventions in patients with cancer has been the subject of considerable debate because of the concern that the provision of nutrients may stimulate tumor growth and metastases. EN is associated with improvements in nitrogen balance and consistent weight gain. PN consistently leads to weight gain, increases in body fat, and improved nitrogen balance. Neither EN nor PN has demonstrated improvements in serum protein levels.[66]

Enteral nutrition is recommended in patients with a functioning GI tract in whom oral intake is inadequate to meet energy requirements. Contraindications include a malfunctioning GI tract, severe diarrhea or bleeding, mechanical obstructions or malabsorption, GI fistulas, or intractable vomiting.[81]

ASPEN is a multidisciplinary organization dedicated to improving patient care through the advancement of the science and practice of nutritional support therapy. ASPEN has developed evidence-based guidelines outlining specific recommendations for nutrition support therapy during adult anticancer treatment and HSCT. The ASPEN recommendations for patients receiving anticancer treatment and those for undergoing HSCT are outlined in Tables 90-3 and 90-4, respectively.[66]

The use of nutritional support therapy during routine cancer treatment, including surgery, chemotherapy, or radiation, has not been shown to improve outcome. Nutrition support therapy is appropriate for subsets of these populations who are malnourished or at risk for malnutrition, but this should only be instituted as part of a nutrition care plan that is developed after a formal nutritional assessment is completed. EN and PN can both be used in the setting of HSCT to support nutritional status during the peritransplant period. ASPEN recommends the use of nutrition support therapy for patients undergoing HSCT who are malnourished and who will be unable to consume or absorb adequate nutrients for a prolonged period of time to minimize the complications associated with malnutrition. Seven to 14 days is generally accepted as a prolonged period, although this has not been clearly defined in the literature.[66] It is important to note that PN is also associated with a number of complications, including fluid overload, hepatic dysfunction, subclavian vein thrombosis, delays in platelet engraftment, and catheter-related infections. PN may also diminish appetite. Specific contraindications for using the parenteral approach include a functioning GI tract, the need for nutritional support therapy for a period of less than 5 days, lack of adequate vascular access, hemodynamic instability, anuria, profound metabolic or electrolyte disturbances, and patient or caregiver preference.[81]

Symptom Management

Patients with hematologic malignancies experience a variety of symptoms related to both their underlying disease and treatment process.

Table 90-3 ASPEN Clinical Guidelines: Nutrition Support Therapy During Adult Anticancer Treatment

1. Patients with cancer are nutritionally at risk and should undergo nutritional screening to identify those who require formal nutritional assessment with development of a nutrition care plan.
2. Nutrition support therapy should not be used *routinely* in patients undergoing major cancer operations.
3. Perioperative nutrition support therapy may be beneficial in moderately or severely malnourished patients if administered for 7 to 14 days preoperatively, but the potential benefits of nutrition support must be weighed against the potential risks of the nutrition support itself and of delaying the operation.
4. Nutrition support therapy should not be used *routinely* as an adjunct to chemotherapy.
5. Nutrition support therapy should not be used *routinely* in patients undergoing head and neck, abdominal, or pelvic irradiation.
6. Nutrition support therapy is appropriate in patients receiving active anticancer treatment who are malnourished and who are anticipated to be unable to ingest or absorb adequate nutrients for a prolonged period of time.
7. The palliative use of nutrition support therapy in terminally ill cancer patients is rarely indicated.
8. Omega-3 fatty acid supplementation may help stabilize weight in cancer patients on oral diets experiencing progressive, unintentional weight loss.
9. Patients should not use therapeutic diets to treat cancer.
10. Immune-enhancing enteral formulas containing mixtures of arginine, nucleic acids, and essential fatty acids may be beneficial in malnourished patients undergoing major operations.

ASPEN, American Society for Parenteral and Enteral Nutrition.

Table 90-4 ASPEN Clinical Guidelines: Nutrition Support Therapy During Adult Hematopoietic Cell Transplantation

1. All patients undergoing hematopoietic stem cell transplantation (HSCT) with myeloablative conditioning regimens are at nutritional risk and should undergo nutrition screening to identify those who require formal nutritional assessment with the development of a nutritional care plan.
2. Nutrition support therapy is appropriate in patients undergoing HSCT who are malnourished and who are anticipated to be unable to ingest or absorb adequate nutrients for a prolonged period of time. When parenteral nutrition is used, it should be discontinued as soon as toxicities have been resolved after stem cell engraftment.
3. Enteral nutrition should be used in patients with a functional GI tract in whom oral intake is inadequate to meet nutritional requirements.
4. Pharmacologic doses of parenteral glutamine *may benefit* patients undergoing HSCT.
5. Patients should receive dietary counseling regarding foods that may pose infectious risks and safe food handling during the period of neutropenia.
6. Nutrition support is appropriate for patients undergoing HSCT who develop moderate to severe GVHD accompanied by poor oral intake and/or significant malabsorption.

Symptoms may occur concurrently or in clusters and cause patients significant distress. The symptom burden is the combined impact of all disease- or therapy-related symptoms on the patient's ability to function. In the hematopoietic population, physical symptoms occur frequently and include pain, mucositis, nausea, vomiting, diarrhea, and delirium.[104] Cancer treatment, particularly aggressive, multimodality interventions, can be extremely stressful for patients and often result in psychosocial distress. Psychologic symptoms occur frequently in patients with hematologic cancers and include anxiety, depression, grief, loss, and feelings of demoralization.[105] Symptom severity and the cumulative effects of symptom clusters can be indicators of nutritional risk.[106] To preserve optimal nutritional intake and function, it is essential that nutrition-impact symptoms be anticipated and proactively managed regardless of the outcome of underlying disease. The management of symptoms that have the potential to interfere with oral intake is a critical component of a nutritional care plan. Selected interventions to manage some of the common nutrition-impact symptoms in patients with hematologic malignancies are shown in Table 90-5.

Pharmacologic Interventions

Current treatments for cachexia include the use of agents that affect either appetite or cachectic mediators or signaling pathways. Empirical evidence supports only a limited number of pharmacologic interventions in the management of anorexia. Corticosteroids are recommended for patients in whom short-term benefit is needed or those with a limited life expectancy. Progestins, such as megestrol acetate, have been extensively studied for their orexigenic effects. More than 15 randomized clinical trials of high-dose progestins have been completed demonstrating statistically significant improvements in appetite and body weight; however, body composition analysis has indicated that the weight gain associated with these agents is related to increased fat and not lean body mass.[71] Cannabinoids and hydrazine sulfate have also been investigated, but in a recent review, the effectiveness of these agents could not be demonstrated.[32] Ghrelin, a neuropeptide released from the stomach in response to fasting, has been shown to stimulate energy intake by approximately 30% in patients with cancer and anorexia without side effects. Further studies are needed to determine if ghrelin increases lean body mass and weight. RC-1291, a ghrelin mimetic, is currently being investigated in the setting of cancer-induced anorexia. This agent has been shown to increase lean body mass and improve hand grip strength; no changes in quality of life or weight have been reported.[71]

Several mediators of cachexia signaling pathways have also been investigated to determine their effect on weight gain and a number of other outcome variables. Eicosapentaenoic acid (EPA) is an essential omega-3 fatty acid that is found in oily fish such as salmon, mackerel, and sardines. EPA has been found to attenuate muscle atrophy and stimulate appetite. Empirical evidence supports stabilization of body weight in patients with cancer, although poor compliance has been an issue for patients participating in these studies. β-Hydroxy-β-methylbutyrate (HBM) is similar to EPA in that it attenuates PIF-induced protein degradation in muscle by downregulating the ubiquitin–proteasome pathway. It also plays a role in the depression of protein synthesis. In placebo-controlled trials, when HBM was administered in combination with L-glutamine and L-arginine, increased body weight and lean body mass were reported, but no change in fat mass was demonstrated.[71]

Thalidomide is a cyclic imide that has been shown to decrease the stability of mRNAs coding for different proinflammatory cytokines, including TNF-α.[107] Thalidomide has now been used in several clinical trials aimed at evaluating its effectiveness in the treatment of cancer-related anorexia and cachexia. In a small preliminary study, thalidomide has been shown to improve symptoms, including nausea, appetite, sensation of well-being, and restedness in the morning.[108] Another early investigation evaluating the use of an isocaloric diet in combination with thalidomide demonstrated increases in body weight and lean body mass in patients with solid tumors. In this study, the agent was well tolerated, with no patients developing neuropathy.[109]

Several other compounds that have the ability to inhibit cytokine production have been investigated for their potential use in the setting of cachexia. Atractylenolide (ATR) is an agent that has been used in Chinese traditional medicine to improve GI symptoms such as nausea, vomiting, and anorexia. Recent evidence has demonstrated its ability to markedly decrease circulating IL-1, and in a randomized,

Table 90-5 Practical Interventions and Patient Education for Nutrition-Impact Symptoms

Symptom	Selected Interventions
Anorexia	Avoid drinking liquids with meals; instead drink liquids in between meals. Avoid large meals; six smaller meals are usually better tolerated. Keep high-calorie, high-protein snacks on hand, such as peanut butter, ice cream, cheese, and granola bars. Avoid consuming empty calories such as sod, fast food, and processed snacks. Stimulate appetite with light exercise, wine or beer (if not contraindicated), orexigenic agents as prescribed. Add extra calories and protein such as butter, skim milk powder, wheat germ, brown sugar, or honey to food.
Mucositis	Avoid tart or citrus foods, tomato-based foods, and pickled or vinegary foods. Avoid spicy foods, hot sauces, and spices such as pepper, cloves, chili powder, and nutmeg; other seasonings such as basil, thyme, and oregano are less irritating and may be better tolerated. Avoid caffeine, alcohol, and tobacco; these substances cause dryness and irritation. Choose soft-textured foods such as creamy puddings, cream soups, custards, soft eggs, cooked cereals, mashed potatoes or other root vegetables, casseroles, ice cream, puddings, and yogurt. Avoid hard, rough foods such as toast, crackers, pretzels, and granola. Moisten dry foods with gravies or sauces.
Nausea	Take antiemetics as prescribed. Eat small, frequent meals rather than three larger meals. Avoid overly sweet, salty, greasy, fried, or rich foods. Consume foods that are not associated with strong odors. Eat dry foods such as saltines, pretzels, or bread sticks every few hours during the day. Rest with the head elevated for at least 1 hour after consuming foods.
Taste changes	Use plastic utensils to minimize a bitter or metallic taste. Substitute high-protein foods for red meats in patients who are experiencing taste aversions to meat. Substitute foods may include fish, poultry, Greek yogurt, milkshakes, high-protein milk, soy products, eggs, cheese, puddings, whole grains, and ice cream. Rinse mouth with water, salt water, tea, or ginger ale before eating to help clear and stimulate taste buds. Use cool rather than warm or hot foods. Freeze foods such as grapes, cherries, watermelon, and oranges for snacks. Use tart flavors such as lemon or citrus; tart hard candies such as lemon drops may reduce bitter or metallic taste. Mints or chewing gum may help get rid of unpleasant tastes in the mouth.
Xerostomia	Drink 8 to 12 beverages per day. Use a straw to drink liquids. Moisten dry food with sauces or gravies. Avoid commercial mouthwashes, alcohol, and acidic beverages. Eat soft or moist foods at cool or room temperature. Take small bites and chew food completely.

nonblinded pilot study involving a small sample of patients with cancer, ATR was shown to significantly increase body weight and arm circumference.[110] Cytokine-neutralizing agents, such as the monoclonal antibody infliximab (Remicade, Janssen Biotech) or soluble receptors such as etanercept (Enbrel, Amgen, Pfizer), which both target TNF-α, are used to treat other chronic inflammatory pathologies and have been shown to increase weight and lean body mass in patients with rheumatoid arthritis. Little information about the use of these agents in the setting of cancer cachexia is available in the literature, although a number of trials are underway. An alternative approach to treating patients with cancer associated cachexia is the use of small molecule inhibitors of Janus kinase 1 (JAK1) and JAK2. Although these drugs are frequently not active against the underlying malignancy, their use in this scenario is directed toward interrupting tumor-associated cytokines that result in cachexia. This approach is currently being explored in patients with far advanced pancreatic cancer. Although these and other molecules that block cytokine production or interfere with the proposed mechanisms of cachexia hold promise, none of them are currently available for routine use in cancer patients. Moreover, the use of these agents in patients with hematologic malignancies will require careful consideration because they have the potential to influence immune response.

FUTURE DIRECTIONS

Hematologic malignancies comprise a heterogeneous group of diseases that entail diverse therapeutic interventions. The malignancies, as well as the interventions used to treat them, are associated with toxicities that can profoundly influence nutritional status. Nutritional issues span the continuum between malnutrition and overnutrition in this population, and both of these alterations have the potential to negatively influence patient outcomes. Additional research on nutritional issues within the hematologic malignancies population is needed. Particular areas of focus should include descriptive work detailing the incidence, prevalence, and etiologies of nutritional issues within patient subgroups as well as investigations of the effectiveness of novel nutrition support interventions and their influence on overall outcomes. Additionally, as emerging therapeutics continue to shift survival rates among these populations, there will be growing need to understand the enduring effects of nutritional alterations on survivors of hematologic malignancies.

CHAPTER 91

PSYCHOSOCIAL ASPECTS OF HEMATOLOGIC DISORDERS

Ruth McCorkle and Elizabeth Cooke

Major changes in the understanding and treatment of cancer have led to increased survival for people diagnosed with hematologic cancers. Regardless of the advances and concomitant survival increase, a diagnosis of a hematologic malignancy can have great impact on the psychosocial aspects of the lives of cancer survivors and their families. Diseases of the blood are perceived as serious and often fatal. Psychologic, existential, cognitive, social, and economic stressors are common experiences for cancer survivors. Despite the increasing attention by providers, policy makers, and the general public on long-term survivorship issues within the past 20 years, ongoing progress must continue to be made in identifying and testing interventions and services to meet the psychosocial aspects of quality cancer care for patients and their families.[1,2] Psychosocial interventions and services are those that enable patients, their families, and health care providers to optimize health care and health care outcomes by managing the psychologic, social, and behavioral aspects of cancer and its consequences.

These psychosocial aspects may be intensified in patients with hematologic malignancies because of their association with an uncertain prognosis, a prolonged treatment course often involving numerous hospitalizations, and the systemic nature of the diseases.[3] Discomfort from painful medical procedures, body image disturbances, central line catheters, sexual dysfunction, and role and relationship disruptions resulting from lengthy hospitalizations and fear of premature death are just a few of the issues that confront patients, highlighting the necessity for monitoring of their psychosocial needs. Involvement with a complex and fragmented health care system, the need for episodic and aggressive treatment, remissions and exacerbation of acute and distressing symptoms, functional limitations, family separation, financial burden, and role disruptions are a few of the issues that characterize the life of patients with hematologic malignancies, not to mention the threat to life imposed by these diagnoses. This chapter provides information on factors that affect psychosocial adjustment among patients with hematologic malignancies, the wide range of psychologic responses that are possible throughout the illness trajectory, and the efficacy of psychosocial interventions and services to minimize distress and promote adaptation. Some practical guidelines regarding patient management and identification of patients who may require formal psychiatric consultation are offered.

ACCOMPANYING TRENDS IN PSYCHOSOCIAL ISSUES

Within the past 25 years there have been significant advances in oncology that have affected the psychosocial care of the cancer patient. The continued advances in quality-of-life research, survivorship, personalized medicine, and quality care initiatives; interest in the reduction of health care disparities, evidence-based medicine, and palliative medicine; and the increasing interest in psychosocial health for patients and caregivers are a few of the changes in cancer care.

Interest in health-related quality of life can be traced back to 1947 with the beginning of the first nonphysiologic outcome measure for cancer: the Karnofsky performance scale. Exponential growth in disease-specific and individual-specific tools for measurement of health-related quality of life continues to this day.[4,5] Since the beginning of the survivorship movement, there has been increasing growth in legislation, education, and advocacy for cancer survivors. The focus on personalized medicine coupled with an interest in decreasing health care disparities has incorporated the idea of tailoring interventions to the needs of individual patients.[6-8] The emergence of palliative medicine, a new specialty that overlaps symptom management and end-of-life care with oncology specialists has made an impact on improving symptoms in oncology patients.[9] The Institute of Medicine report *Cancer Care for the Whole Patient: Meeting Psychosocial Health Needs* lists 10 recommendations related to improving psychosocial health for patients and family members.[10]

CLINICAL COURSE OF HEMATOLOGIC MALIGNANCIES

The incidence, course, treatment, and survival for various hematologic malignancies vary widely. New cases of multiple myeloma are estimated to be 21,700, with dramatic improvements in treatment and 5-year survival rates from 25% in 1975 to 34% in 2003.[11,11a] Myelodysplastic syndromes occur in 5 per 100,000 individuals, and recent prognostic stratification has been able to determine those patients who have increased survival.[12] The median age of onset for chronic myeloid leukemia is 67 years with an estimated 5430 cases diagnosed in the year 2010 with 610 deaths.[13-16] The translocation between chromosomes 9 and 22 results in the Philadelphia chromosome marker for chronic myeloid leukemia. The disease evolves from a chronic phase to an accelerated phase and finally an acute phase, which looks similar to acute leukemia in its presentation and intensity. Recent newer tyrosine kinase inhibitors have transformed the treatment, response, and prognosis for chronic myeloid leukemia.[13-16] Close to 13,780 individuals will be diagnosed with acute myeloid leukemia in 2010 with approximately 10,200 patients dying of the disease.[17] As the population has increased in age, the incidence of acute myeloid leukemia has been also rising.[17] Hodgkin disease is uncommon with an incidence of approximately 9000 cases per year and 1320 deaths per year.[18] The cure rate is 80% with an improved 5-year survival over the past decades.[18] Non-Hodgkin lymphoma is a heterogeneous group of lymphomas with an incidence of 66,000 cases and a death rate of approximately 19,000.[19-21] The incidence has been increasing dramatically in the past decades for two main types of non-Hodgkin lymphoma: B-cell and T-cell lymphomas. A new classification system and better imaging with positron emission tomography–computed tomography (PET-CT) have better tailored the treatment combinations such as chemoimmunotherapy and radioimmunotherapy. In contrast to treatment of many solid cancers, treatment of hematologic malignancies often involves intense regimens, highly technical therapies, lengthy hospitalizations, episodes of high infection risk, periods of unpredictability, and ongoing outpatient monitoring of the patient's condition. A number of patients respond to the curative attempts with long-term remission, remain well, and, after a period, are considered cured. However, some patients have a positive response to a curative attempt but then relapse. Other patients begin treatment with a hope for a cure but do not respond and progressively decline. In some patients, the disease is too far advanced when diagnosed, and they experience a

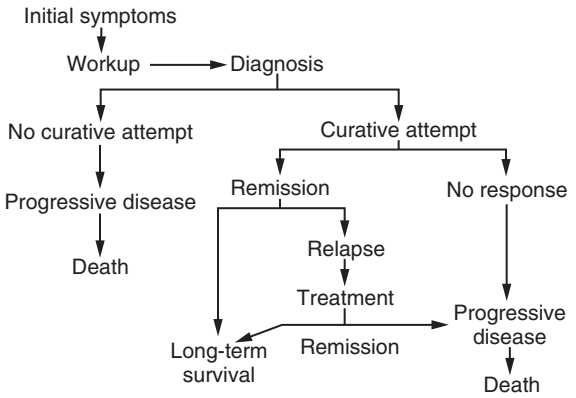

Figure 91-1 CLINICAL COURSE OF A PATIENT WITH A HEMATOLOGIC MALIGNANCY. *(Modified from Lesko LM: Hematopoietic dyscrasias. In Holland JC, editor:* Psychooncology, *New York, 1998, Oxford University Press, p 408.)*

Factors That May Predict Poor Coping in Patients With Cancer

- Past psychiatric history
- Compliance issues
- Demographic factors such as younger age and female sex
- Limited social support or difficult social relationships
- Recent history of smoking cessation
- Substance abuse history
- Recent losses
- Advanced disease
- Uncontrolled symptoms
- Pessimistic outlook on life
- Multiple obligations
- Avoidance coping (escape-avoidance, distancing, and denial)
- Lower functional status
- Higher regimen-related toxicity
- Treatment

rapid progression of their disease. The remainder of this chapter proceeds through the common trajectories associated with hematologic malignancies including diagnosis, treatment, relapse, the end of life, and survivorship (Fig. 91-1).

Time of Diagnosis

Being diagnosed with a hematologic malignancy can be a devastating time of crisis. The time of diagnosis has been described by a cancer survivor as "a lightning bolt through a stop sign."[22] It is a time of intense stress and likened to a personal disaster in the patient's and family's life.[23] Often these patients describe vague symptoms such as fatigue for weeks, even months, or they are treated in urgent care centers for bronchitis or other infections only to be diagnosed with an unexpected catastrophic illness such as leukemia. Weismann and Worden[24] described the first 100 days after diagnosis as an "existential plight." They documented that patient concerns initially focused on existential issues of life and death more than on concerns related to health, work, finances, religion, self, or relationships with family and friends. The period from time of diagnosis through initiation of treatment is characterized by sometimes fast-paced medical evaluation and treatment, the development of new relationships with unfamiliar medical personnel, and the need to integrate a barrage of information that is at best frightening and confusing. Often patients with hematologic malignancies need immediate treatment intervention compared to those patients with solid tumors. But even with the advanced speed of information in this technologic age, patients have difficulty with information integration in a short period of time. Within the context of this anxiety-provoking situation, timely decisions must be made regarding treatment, and patients may feel tremendous responsibility, concern, and isolation during this period.

Initial response to a diagnosis may be profoundly influenced by a person's prior experience with cancer.[25] Those with memories of close relatives with cancer often demonstrate heightened distress, particularly if the relative died or had negative treatment experiences. During the diagnostic and early treatment periods, patients may search for explanations or causes for their cancer and may struggle to give personal meaning to their experience.[26] Because many clinicians are guarded about disclosing information until a firm diagnosis is established, patients may develop highly personal explanations that can be inaccurate and provoke intensely negative emotions. Ongoing involvement and consistent and repeated information from key health care providers help to minimize patients' uncertainty and the development of maladaptive coping strategies based on incomplete or inaccurate information.

Although extreme and sustained psychologic reactions as the first response to a cancer diagnosis are unusual, careful assessment of the nature of the patient's reaction remains important. Initial reactions often are predictive of later adaptation.[27,28] Early assessment by clinicians can help to identify people who are at risk for later adjustment problems and in greatest need of ongoing psychosocial support[29-34] (see box on Factors That May Predict Poor Coping in Patients With Cancer). Although the literature substantiates the devastating psychologic impact of a cancer diagnosis, it is also well documented that many patients cope effectively. Positive coping strategies, such as taking action and finding favorable characteristics in the situation, have been reported as effective. Maintaining optimism[35] and having an active determination to recover have been associated with positive adjustment. Contrary to the beliefs of many clinicians, denial has also been found to assist patients in coping effectively with a diagnosis of cancer, unless used to an excessive degree. With the firm establishment of the cancer diagnosis, planning for treatment begins. If patients have been given a clear explanation of their condition while encouraged to maintain hope, the initial reaction of shock, fear, and desperation can give way to a sense of optimism. Health care providers have an important role in monitoring and possibly mediating psychosocial adjustment. Keeping patients informed and actively involved in their care and being aware of the unique meaning that people may associate with a diagnosis of cancer are vital. Patients who have a pervasive and unyielding negative affect that persists long after the crisis of diagnosis may require ongoing psychosocial monitoring and referral for services and supportive interventions throughout their treatment and disease course.[36]

In addition, family assessment during this phase is vital. Levels of family distress, depression, and anxiety are mediated by the functioning of the family at the time of diagnosis.[37] Studies have shown that caregivers and families share similar rates of psychosocial angst.[37,38] Families who have open expression of feelings and actions have reported lower depression; however, those families who have dysfunctional problem-solving abilities have higher depression.[37] Also, anxiety within the family increases with unclear communication.[37] Both anxiety and depression are easy to assess in patients and family members, and timely referral for assistance during this period may lay a foundation of adequate coping throughout the patient's course of illness. During this time, many providers are conveying large amounts of information. It is not always easy for patients to differentiate the importance of each communication and prioritize their problem-solving behaviors. Consequently, providers must repeat information at each contact and inquire about the patients' and families' understanding of facts and treatment options. Often patients and families describe that they are in a state of numbness and that information is not really processed, understood, or comprehended.

Psychosocial factors are critical parameters in considering which treatment is best for an individual patient. The development of a treatment plan should include information about all aspects of

medical/surgical treatments as well as what is known about the psychosocial sequelae. Often, patients react to a diagnosis of cancer with feelings of fear and helplessness. Patients look to the primary oncologist for a curative treatment that also can preserve their quality of life. Patients may feel vulnerable and believe that complete reliance on the oncologist is essential. Combating feelings of helplessness during this period can help patients alleviate painful anxiety. This is best done by a member of the health care team who has established a treatment alliance with the patient. The health care provider must make the patient feel like a partner in all aspects of care. This is especially true regarding decisions about treatment options. Giving information to patients and families often alleviates anxiety and uncertainty because patients feel more in control.

Active treatment of cancer usually initiates another acute phase of the cancer experience. It can occur while a patient is receiving treatment or as a complication of treatment. An important standard of clinical practice, based on extensive research, is to provide patients with information that will prepare them for what to expect during their treatment. Research by Johnson[39] provides convincing evidence that patients who receive specific information about the nature, pattern, and timing of treatment side effects report less disruption in activity than those who are not given this detailed information. Some providers wait until patients complain about potentially expected side effects. When this happens, patients may become skeptical about the completeness or accuracy of any future information given by the person. This threat to undermine a trusting relationship has important implications for decision making, patient choice of care setting in the future, and recommendations made by patients to others who are seeking a source of cancer care.

Often during the treatment phase increasing burdens are placed on the immediate caregiver and family to support the patient's schedule for treatment, multiple admissions, and increasing dependency.[40] The patient may be unable to work, and financial stressors accumulate. Sensitivity and awareness by providers to social, economic, and relationship stresses are needed to assist with referral for social services and other psychologic assistance. Support groups with other patients can be helpful during this time. Evidence clearly indicates that sharing a common experience in a support group can have psychologic benefit.[41]

DECISION FOR HEMATOPOIETIC STEM CELL TRANSPLANTATION

Hematopoietic stem cell transplantation (HSCT) is standard treatment for many high-risk hematologic malignancies and nonmalignant diseases either as part of overall treatment or after relapse. Both autologous and allogeneic transplant numbers are increasing worldwide.[42] The procedure for transplantation is complex and can cause intense psychologic distress and extreme social strain on the patient's caregiver, friends, and family members. Often the psychologic and social issues can be more challenging for the health care team than the medical issues. Because HSCT is an intense and distinctive experience for patients and families and has the potential to cause prolonged psychologic distress unlike other experiences with oncology patients, the issues unique to this population warrant a separate discussion.[43,44]

HSCT patients face physical and psychologic stresses of hospitalization and social isolation for weeks to months during their initial recovery. Consequently, a thorough pretransplant psychosocial evaluation is recommended to identify those patients at risk for development of psychosocial morbidity and to initiate timely interventions to optimize adaptation. Identified risk factors for psychosocial morbidity following transplant include previous psychiatric morbidity, pretransplant compliance issues, pretransplant physical and mental health problems, younger age, female sex, avoidant coping style, recent smoking cessation, lower functioning status on admission, problems with quality and presence of social support before transplant, perception of limited social support, the presence of difficult relationships, and professional integration concerns.[29,31]

The time of transplantation when the infusion of cells occurs can be a special moment for patients, with patients often referring to the date of transplant as a "birthday" or special anniversary date. Often family members are gathered at the bedside to celebrate the long-awaited event of the transplant. However, the weeks following transplant can be difficult psychologically. Additional factors that need close monitoring include persistent symptoms following transplant, increased regimen-related toxicity, slower physical recovery, chronic graft-versus-host disease (GVHD), negative appraisal of the transplant experience, body image disturbance, fears of relapse and secondary malignancies, and sexual function disruption.[44-47] The threat of death continues to be real, and patients experience social isolation, bodily discomfort, major body image changes, and a sense of loss of control. These issues lead to a myriad of emotions, including hope, anger, depression, anxiety, anticipation, guilt, and joy.[44]

Khan et al[48] identified the following common psychiatric diagnoses with inpatient transplant patients: adjustment disorder (40%), depression (23%), generalized anxiety disorder (10%), acute psychotic disorder (10%), delirium (10%), and depressive psychosis (7%). Kishi et al[49] compared inpatient psychiatric consultations among transplant and nontransplant patients. Transplant patients differed on several characteristics: more frequently white, less likely to have a previous psychiatric history, longer time period between admission to consult, more delirium, and more socioeconomic and health-related distress.

Patients are often not prepared for the long, gradual recovery. Patients are more familiar with recovery after surgery that takes days to weeks, and they are unprepared for and overwhelmed with the long recovery that can take weeks to months or even months to years. Typically patients perceived their quality of life to be worse the first year after transplant than before transplant.[50] Patients continue to feel functional limitations, and both autologous and allogeneic patients report common somatic symptoms, especially fatigue, the most common distressing symptom.[51-53] Patients who experience depression the first year have a higher mortality rate.[54] Periods when patients are particularly psychologically vulnerable during the first year include admission workup, directly before transplant, discharge from the inpatient setting, between 3 and 5 months, and between 6 and 9 months.[27,55] Other factors that have been identified as related to psychologic distress and poor health after transplantation include pre-HSCT psychologic and physiologic status, anxiety, depression, poorer quality of life, disease recurrence, negative mood, type of transplant, locus of control, low social support, presence of GVHD, and caregiver/family distress.[44,51,52,56] The financial burden for patients who undergo bone marrow transplantation (BMT) can be overwhelming, including medical expenses for the patient and marrow donor in the case of an allogeneic BMT, potential travel expenses, and loss of income for other family members.[41] Patients and their immediate families often are geographically far from their usual support systems because of the distance to the BMT center. In some cases, family members who have not been close in the past may be forced to interact with each other, leading to additional stress.

Although the literature is clear that most patients return to a productive life with high quality of life, during the first few years after transplantation, patients and family members may continue to experience physical and psychologic sequelae.[57] One study reported that 43% of patients with an average of 3.4 years after transplant had clinically significant global psychologic distress.[58] Despite this distress, only 50% of the patients received mental health services.[59]

Researchers have described the following factors as predictors of poorer quality of life in patients 1 to 5 years after transplant: younger age, long-term sequelae, chronic GVHD, unemployment, lower income, poor functional status, and short follow-up by the treatment center.[50,60] Patient and families are ready to put the experience behind them, only to discover that the experience of transplant has forever changed the patient's outlook, priorities, and family network. Fear of recurrence and feelings of uncertainty related to future relationships, work, and financial strain continue.[41] There is discordance between the patients' pre-HSCT expectations and the everyday symptoms that limit their physical abilities. Besides fatigue, which continues to be

the dominant symptom, another distressing issue is cognitive dysfunction as patients return to the workplace or reenter school.[41] Educating patients about some expected common short-term side effects can reduce anxiety. Neurocognitive side effects of treatment can be long term in high-risk patients but are mostly temporary, including diminished concentration, short-term memory loss, decreased speed of information processing and loss of effective problem-solving abilities. Sexuality issues are another area of great concern for patients in the posttransplant period. Barriers for discussion and lack of referrals for supportive services in this area may be related to the patient's embarrassment, the clinician's lack of knowledge, or the focus on other issues that may be interpreted as more critical. Common sexual issues after transplant include vaginal dryness and distressing menopausal symptoms in women and erectile dysfunction in men.[61]

Patients who experience physical symptoms after transplantation may be at risk for long-term psychologic distress.[40] Despite the fact that patients are followed by transplant physicians longer than patients with nonhematologic malignancies, this population often is referred back to primary care physicians 1 to 2 years after transplant. Primary care clinicians do not have the knowledge or experience to recognize physical complications related to the effects of chemotherapy, radiation, and GVHD, so ongoing communication between the providers and the transplant team and center is imperative. Long-term effects may include persistent viral, bacterial, and fungal susceptibility, GVHD, dental caries, muscle atrophy, pneumonitis, gonadal dysfunction, sexual dysfunction, endocrine abnormalities, cataracts, ocular sicca syndrome, reduced bone mass, secondary malignancies, and cognitive dysfunction.[62] In addition to monitoring physical complications, the American Society for Blood and Marrow Transplantation consensus statement recommends annual evaluation of patients' psychologic status. Health care providers must have a high level of vigilance to assess depression in both the patient and family caregiver years after transplant, with clinical assessments recommended annually after transplant. Studies of transplant survivors beyond 10 years indicate possible issues with returning to work, physical fitness, impairment in social functioning and family life, insurance denial, and continued symptoms such as pain, depression, muscle stiffness/cramps, memory/attention problems, sleep disorders, sexual issues, and incontinence.[63,64] In spite of the range of problems, only 9.8% of patients reported accessing psychologic support.[63]

The concept of posttraumatic growth (PTG) after transplantation has been evolving. By definition, the potential for PTG requires that patients experience a stressful event and subsequently experience positive psychologic outcomes or benefits. As early as 1996, Fromm identified that positive sequelae are possible after transplantation, including the development of a new philosophy of life, greater appreciation of life, making changes in personal characteristics, and improving relationships with family and friends.[64a] Potential predictors of PTG among posttransplant patients include good social support, little avoidance coping, younger age, less education, greater use of positive reinterpretation, problem solving, seeking alternative rewards, more stressful appraisal of the experience, and more negatively biased recall of pretransplant levels of psychologic distress.[32,65] Discussing the PTG potential with patients and making referrals for counseling to experienced clinicians who are aware of the potential for PTG are essential.

Although patients report long-term psychosocial effects after transplantation, they may be reluctant to accept help and fail to access psychologic resources and social support.[63] These patients must be encouraged to use resources and seek psychologic support, because this experience may impair the patients' and families' ability to cope with life after transplant. In an article about HSCT patients' experiences with a support group, Sherman et al[41] identified the themes of meaning and changing of perspectives as patients expressed their struggles with redefining themselves, their priorities, and their values. Some patients wanted to change their former values and behaviors. The support group experience may be therapeutic for patients who often do not have physical signs of transplant to the untrained eye but continue to experience increasing or unresolved psychologic and physical issues.[29,40] Sharing a common experience may encourage patients to believe that their symptoms and feelings are not unique and may decrease their feelings of isolation.

Immediate Period Following Diagnosis and Treatment

As the treatment and acute side effects improve and subside, patients often feel that the whirlwind has passed, only to be confronted with uneasy silence. Weeks and months of clinic and physician appointments, infusions, and admissions stop or trickle to a small stream of appointments. Families who have been functioning on a grinding schedule of crisis mode find the change almost paralyzing. Adding to this halt of activity, health care providers have a tendency to limit their contacts when the patients' physical status has stabilized. This is a critical time when psychosocial interventions and supportive services from other members of the health care team must be instituted for patients and family members to deal with the uncertainty and anxiety of waiting. Fears and anxieties change from fighting the disease to returning to life.[66] Because of less contact with the primary treatment oncologists, patients and families may perceive a withdrawal of support from the medical team. Long-term psychosocial health of the patient and family is affected by the meaning ascribed to the cancer experience, fear of recurrence, support of the family, demographic factors, and financial stressors. This transition time is pivotal for patients' long-term quality of life. Surveillance with specific questions to access the need for referrals can have lasting outcomes.

Time of Relapse

The time of recurrence of cancer has been reported to be more distressing for patients and family members than the initial diagnosis. The recurrence of the disease can plunge the patient and family into despair and crisis as they realize that death may occur despite the ongoing fight to live. The psychosocial issues experienced by the person with cancer depend in part on the clinical course of the disease process. As the disease progresses, the person often reports an upsetting scenario that includes uncertainty, frequent pain, diminished functional ability, increased dependence, and disability.[25]

The development of a relapse after a disease-free interval can be especially devastating for patients and those close to them. The medical workup often is difficult and anxiety provoking, and psychosocial problems experienced at the time of diagnosis frequently resurface, often with greater intensity.[25] Shock and depression often accompany relapse and require patients and family members to revaluate the future. In spite of the overwhelming nature of the psychosocial responses, however, most patients do cope effectively with progressive disease, and it is important to recognize that intense emotions do not necessarily equate with maladaptive coping. Investigators studying quality of life in patients with cancer have demonstrated a clear relationship between a person's perception of their quality of life and the presence of discomfort.[67,68] As uncomfortable symptoms increase, perceived quality of life diminishes. An important goal in the psychosocial treatment of patients with advanced cancer centers on optimal symptom management.

An issue that repeatedly surfaces among patients, family members, and professional care providers is the use of aggressive treatment protocols in the presence of relapse and progressive disease. Currently there are newer agents that can induce remission in the face of relapse. In addition, patients and families often request participation in experimental protocols, even when there is little likelihood of extending survival. Controversy continues about the efficacy of such therapies and the role health care providers can play in facilitating patients' choices about participating. Clear communication about treatment goals and expectations will assist in patient and family preparation.

Certain patients respond to investigational treatment with increased hope. It is vital to clarify the values, thoughts, and

psychologic reactions of care providers, patients, and families to the delicate issues that evolve if individualized care with attention to the patient's psychosocial needs is to be provided.

Survivorship

The definition of a long-term survivor has evolved over time. Initially, individuals who had survived cancer-free for longer than 5 years were considered "survivors and cured." More recently the term *survivors* has been used to define individuals who have completed the acute phase of illness. Others use the term for all patients initially diagnosed with cancer. Some people would prefer changing the term to "thrivers," champions, or fighters.[69]

Successful treatment of hematologic malignancies has resulted in cure for many patients and progressively longer lives for others. However, longer survival is not without significant psychologic sequelae.[70-75] Innovative and new treatments may produce long-term physiologic consequences, such as infertility, treatment-related toxicity, persistent side effects, and organ system failure that can magnify and exacerbate the psychologic issues initially associated with diagnosis and treatment.[67,68,76] The overwhelming evidence from the literature involving survivors with hematologic malignancies is that, on the average, most do very well after the initial adjustment in the first 1 to 3 years after treatment.[50,71] Most long-term BMT survivors express satisfaction with their quality of life and describe themselves as productive, stable, and well adjusted without significant physical, functional, psychologic, and social problems related to their disease or BMT treatment. However, there is a group of patients with a high rate of psychosocial morbidity who are vulnerable to ongoing and intermittent psychosocial distress. Empiric evidence showed that as many as 9% to 30% of long-term survivors with hematologic malignancies experience significant psychologic distress, including anxiety, depression, and posttraumatic distress symptoms.[72,74,77]

Psychologic aspects of survivorship may include concern over termination of treatment; fear of relapse; preoccupation with somatic symptoms; reentry into previous roles; lingering affinity with death; and financial, job, and insurance difficulties. These issues may manifest in a variety of ways, including denial of past illness, leading to medical compliance issues; ongoing problems with anxiety, panic, and depression; and inability to reenter or modify previous roles. Fear of recurrence by both patients and family members can severely affect quality of life.[66] In her classic article "The Enduring Seasons in Survival," Dow[23] stated that the season of extended survival is dominated by fear of recurrence. In fact, Baker et al[51] showed in a group of cancer survivors that "being fearful my illness will return," "concern about relapsing," "fears about the future," and "difficulty making long-term plans" were a problem 68%, 60%, 58%, and 41% of the time, respectively. Mellon and Northouse[78] found that the strongest predictors of quality of life 1 to 5 years after treatment were concurrent family stressors, family social support, family member fear of recurrence, family meaning of the illness, and patient's employment status.

There is increasing interest in patients' experiences with posttraumatic stress disorder (PTSD). Studies have consistently described a higher incidence of PTSD in patients with hematologic malignancies than in the average population.[79-81] Predictors of PTSD severity among patients with hematologic diagnosis include higher levels of distress and high avoidance coping coupled with low social support.[32] These researchers describe how providers can assess coping and presence of family support and potentially mitigate the effects of a distressing experience with the cancer diagnosis. Considerable evidence indicates that the wide range of surgical, chemotherapeutic, and radiation therapies leaves permanent damage to organs and physiologic functioning and disfigurement across the different hematologic diagnoses (Table 91-1). Health care providers should be mindful of psychologic sequelae among patients, even within the context of remission and a hopeful prognosis, and refer patients and family members to a mental health specialist for further evaluation, as needed.

Table 91-1 Long-Term Consequences of Therapies for Hematologic Cancers

Anxiety
Depression
Fear of recurrence
Disfigurement
Conditioned nausea and vomiting
Unemployment
Denial of life insurance
Denial of health benefits
Increase in life insurance rates
Difficulty changing health care coverage
Breakdown of marriage or relationship
Decline in participation in leisure activities
Diminution of support from others
Disruption in sexual functioning
Fertility

Terminal Stage and End-of-Life Care

Technologic advances in health care have improved the potential for cure of many previously fatal hematologic malignancies. However, many patients still have disease that is unresponsive to treatment, continues to progress, and is considered incurable. When cure is acknowledged to be impossible and alternative efforts to combat the progress of disease are exhausted, patients are recognized as terminally ill or dying. In this situation, some authors advocate a palliative care approach with no active treatment and a shift in the emphasis of medical care from the pursuit of cure to supportive and hospice care, including the provision of care and comfort, control of distressing symptoms, and maintenance of quality of life at an optimal level.[82-84] However, this paradigm currently is shifting in the field of palliative care to one of initiating palliative care alongside curative treatment with the philosophy that it should be implemented across the illness trajectory, with the promotion of quality of life to facilitate relief of suffering.[85] The new World Health Organization definition states: "Palliative care is an approach to care which improves quality of life of patients and their families facing life-threatening illness, through prevention, assessment and treatment of pain and other physical, psychologic, and spiritual problems."[86]

Palliative care began with the hospice movement. Since the concept of hospice was first introduced in England in the 1960s, hospice care has been recognized as the state-of-the-science end-of-life care, and hospice services now are available around the world. However, hospice care has not been integrated into the care of patients dying with hematologic malignancies.[87,88] Despite the strong emphasis on providing end-of-life care in accordance with patients' wishes and empiric studies showing that most terminal patients prefer spending their final days of life and dying at home, hematologic malignancy is the only diagnosis that has been repeatedly and consistently shown to predict hospital death.[89,90]

The reasons for such insufficiency have been attributed to many factors. Manitta et al[91] in their article "Palliative Care and the Hemato-Oncologic Patient: Can We Live Together?" identified barriers between the expectations of two specialities: (1) the dying trajectory can be rapid with more unpredictability and more technology, (2) the various hematologic diagnoses are not uniform in response and treatment, (3) the goals of care can be unclear, (4) the focus on cure can preclude the focus on palliation, (5) lack of knowledge exists among hematologists about palliative care principles, and (6) the health care system does not encourage collaborative care. Health care providers, first and foremost, must examine their own attitudes toward death and dying and avoid imposing their own values on patients and their families. Respecting patient and family wishes, appropriately managing and alleviating distressing symptoms, and providing care tailored to meeting patients' needs can help patients

dying of hematologic malignancies reach the end of life with peace and dignity.

FACTORS THAT INFLUENCE PSYCHOSOCIAL ADJUSTMENT

Psychosocial responses to cancer vary widely and are influenced by several factors that clinicians should bear in mind when considering the responses of individual patients. A review of the literature points to key factors that may have an impact on psychosocial adjustment and include individual patient factors, environmental factors, and disease-related factors.

Individual Patient Factors

These factors include demographics, comorbid conditions, previous psychiatric morbidity, previous coping strategies, and stage of the illness. Female sex and younger age have been consistently documented as important predictors for psychosocial adjustment and quality of life for patients with hematologic malignancies.[29,92-94] Also, as the population ages, there are more individuals diagnosed with cancer who already have comorbid diseases.[95,96] These issues complicate treatment decisions and recovery. Patients who have preexisting psychologic issues are acutely at risk for poor psychologic adjustment to the cancer diagnosis.[31,97] Many individual factors are interrelated; for example, a significantly higher anxiety score and more impaired quality of life were observed more in women than in men. The presence of current sleep problems and fatigue were associated with older age at BMT. Poor quality of life after treatment was associated with higher age of the recipient at the time of the transplant, poorer self-image and overall cognitive functioning, and inability to return to work.[73,98-103]

One of the key predictors of psychosocial adjustment to cancer is the psychologic stability of the person before diagnosis. People with a history of poor psychosocial adjustment before development of cancer are at highest risk for psychologic decomposition and should be monitored closely throughout all phases of treatment. This is particularly true of people with a history of a major psychiatric syndrome, psychiatric hospitalization, or both.[31] Also, because a person's coping style is determined relatively early in life and remains stable over time and across situations, it serves as a useful predictor of adjustment to cancer. Several investigators have identified specific personality characteristics, coping strategies, and life experiences that enhance or inhibit positive adjustment to cancer.[104,105] Empiric evidence also demonstrated the beneficial impact of positive coping strategies and personality attributes on long-term survival.[44,106,107] Coping strategies found to be most effective include a "fighting spirit," hopefulness and acceptance of the situation, a belief that life has purpose and coherence, and having a feeling of control over events, resulting in active participation in treatment and engagement in daily life. By contrast, poor adjustment and even PTSD have been associated with avoidant coping strategies, anxious preoccupation and high distraction, prior negative sexual experiences, body image problems, and inhibition in discussing personal and sexual problems.[18] One study showed that patients who smoke are at higher risk for psychiatric morbidity, perhaps due to the potential development of depression and/or anxiety with withdrawal symptoms.[19] It is important to include smoking history in the patient's assessment of substance control use when preparing patients for treatment options.

Environmental Factors

Environmental factors include spouse and family support, other social support, and professional reintegration. The quality of spousal and family relationships has a significant impact on the psychologic health and even mortality of the patient.[108] Social support, network size, satisfaction with social support, and reliance on formal and informal social ties have consistently been found to influence a person's psychosocial adjustment to cancer.[89,90] The ability and availability of significant others in dealing with a diagnosis and discussion of treatment options can significantly affect the patient's view of himself or herself. Patients diagnosed with all types of life-threatening chronic disorders experience a heightened need for interpersonal support. Those who are able to maintain close connections with family and friends during the course of illness are more likely to cope effectively with the disease than are those who are not able to maintain such relationships.[107,109,110]

Traditionally patients are not referred routinely to formal home nursing care at discharge. An initial home visit can be invaluable in assisting patients and families with the transition, in addition to identifying areas in which ongoing assistance is needed. Home care referral can assist families that are increasingly relied on within the current health care system to be the major providers of care outside the hospital.

Disease-Related Factors

Disease-related factors include treatment and toxicity, residual symptoms, appraisal of the disease, treatment and recovery, and fear of relapse. Time interval after treatment has been documented as an important predictor for psychosocial adjustment. Different treatment modalities introduce varying degrees of side effects, symptoms, and impact on quality of life. Significant differences were found between transplant groups with regard to loss of appetite, physical and role functioning, symptom distress, sexual impairment, infertility, mood, and overall quality of life.[27,50,76,103,111-113] Without exception, the greatest difficulties in psychosocial adjustment were observed among patients who underwent allogeneic BMT, followed by autologous BMT recipients, and patients who received conventional or maintenance chemotherapy. The latter groups experienced the least impairment in quality of life and psychologic distress. Patients who underwent transplant also had more psychiatric morbidity if they experienced lower functional status and higher regimen-related toxicity.[31]

Time since BMT or completion of treatment was an important factor for facilitating psychosocial adjustment and improving quality of life. In general, during the first year after BMT, patients perceived their physical and overall well-being as being worst, experienced more anxiety and total mood disturbance, and reported the highest degree of illness intrusiveness in every aspect of life.[27,50,76,103,111-113] With the passage of time, improvements in functional status, quality of life, levels of anxiety, depression, and satisfaction with life were frequently observed after transplant.

Living with a chronic illness often requires continuing care and management by a team of specialists. Use of supportive care services has been related to improved quality of life; therefore it is in the patient's best interest to access services needed for psychologic distress early in the continuum of care.[110] Care usually is provided through follow-up visits to ambulatory or outpatient clinics and consulting rooms, rather than through hospitalization. However, several barriers that may impair the outpatient cancer survivor from accessing health care services include economic and financial constraints.[114] Differentiating a psychiatric complication from expected psychologic responses is imperative.

Although any individual experiencing the crisis of a cancer diagnosis may become clinically depressed or experience a panic attack, most patients do not experience a diagnosable psychiatric condition. Currently the rates of adjustment disorder, depression, anxiety, and PTSD are 40%, 25%, 10%, and 5%, respectively. The ability of health care providers to distinguish expected reactions from more severe psychiatric complications is crucial.

Unfortunately, nonpsychiatric care providers often miss clinically relevant and severe psychiatric syndromes. Being knowledgeable about common symptoms of adjustment disorder, depression, anxiety, and PTSD are helpful. Table 91-2 provides a quick reference; also refer to the *Diagnostic and Statistical Manual of Mental Disorders.*

Table 91-2 Common Symptoms of Psychiatric Disorders

Adjustment Disorder	Depression	Anxiety	Posttraumatic Stress Disorder
The development of emotional or behavioral symptoms in response to an identifiable stressor	Symptoms that are present for a 2-week period and a change from previous functioning	Excessive worry and anxiety for at least 6 months; the person finds it difficult not to worry	The person has been exposed to a traumatic event
1. Marked distress that is in excess of what would be expected for exposure to the stressor 2. Significant impairment in social or occupational functioning	1. Depressed mood most of the day 2. Marked diminished interest or pleasure 3. Significant weight loss or decrease or increase in appetite 4. Insomnia or hypersomnia 5. Psychomotor agitation or retardation 6. Fatigue 7. Feelings of worthlessness or guilt 8. Diminished ability to think or concentrate 9. Recurrent thoughts of death, suicidal ideation, or a plan for suicide	Anxiety and worry have to have three of the six following symptoms: 1. Restlessness 2. Fatigue 3. Difficulty concentrating 4. Irritability 5. Muscle tension 6. Sleep disturbance	1. Reexperiencing symptoms such as images, thoughts, and perceptions 2. Persistent avoidance of stimuli and numbing of general responsiveness 3. Persistent symptoms of increased arousal: sleep issues, anger or irritability, difficulty concentrating, hypervigilance, and exaggerated startle response

Data from American Psychiatric Association: *Diagnostic and statistical manual of mental disorders,* ed 4, Arlington, Va, 2000, American Psychiatric Association.

Another group of patients who are at high risk for developing adjustment problems include those with coexisting severe mental disorders that may include schizophrenia, bipolar disorder, schizoaffective disorder, and obsessive-compulsive disorder. Integrated care of psychiatry and oncology is the best option in treating these patients, first to stabilize the psychiatric illness and then to treat the cancer.[115,116] Good communication, empathy, listening skills, and providing emotional support are all skills that benefit these patients and specifically those who have severe mental illness, who often have a history of disregard and neglect from providers[117] (see box on Screening for Psychologic Distress).

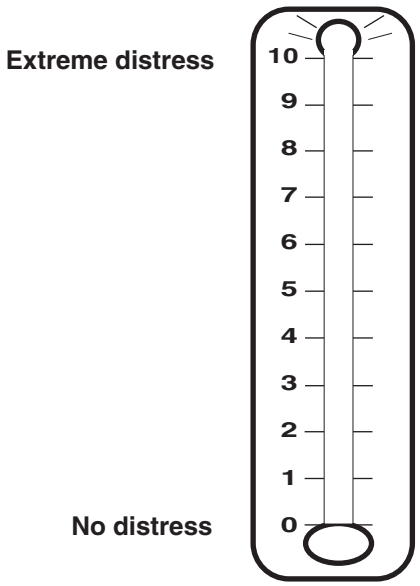
Most patients manifest transient psychologic symptoms that are responsive to support, reassurance, and information about what to expect regarding the cancer course and its treatment. Some require more aggressive psychotherapeutic interventions, such as pharmacotherapy and ongoing psychotherapy. The following guidelines can assist the clinician in identifying those patients who exhibit behavior suggesting the presence of a psychiatric syndrome.

General guidelines designed to assist in distinguishing patients who should be referred for evaluation by a trained psychiatric clinician include the following:

1. History of psychiatric hospitalization or significant psychiatric/personality disorder
2. Persistent refusal, indecisiveness, or noncompliance with regard to needed treatment
3. Persistent symptoms of anxiety and depression that are unresponsive to usual support from health care providers or family members; symptoms may present in the form of constant fear associated with treatment and procedures or excessive crying and feelings of hopelessness that worsen rather than improve with time
4. Abrupt, unexplained change in mood or behavior
5. Insomnia, anorexia, diminished energy out of proportion to expected treatment effects
6. Persistent suicidal ideation
7. Unusual or eccentric behavior or confusion (may be indicative of an organic mental disorder)
8. Excessive guilt and self-blame for illness
9. Evidence of dysfunctional family coping or complex family issues

After referral to a psychiatric specialist, one or a combination of therapeutic modalities may be used. Cancer and its treatment may precipitate an exacerbation of an underlying mental illness to which a patient was predisposed and that may require extensive treatment (e.g., hospitalization for a psychosis, ongoing pharmacotherapy, or psychotherapy). A discussion of these specialized forms of treatment is beyond the scope of this chapter. The reader is encouraged to consult an appropriate standard textbook.[30]

Screening for Psychologic Distress



A number of tools have been developed to screen for psychologic distress, but they have not been consistently incorporated into clinical care.[118,119] One tool that is easy to administer and that patients report as capturing their problems is the *distress thermometer.*[120] The tool is similar to pain measurement scales that ask patients to rate their pain on a scale from 0 to 10 and consists of two parts. The first part is a picture of a thermometer, and patients are asked to mark their level of distress. A rating of 4 or above indicates that a patient has symptoms indicating a need for evaluation by a mental health professional and potentially has a need for referral for services. On the second part, the patient marks items that relate to his or her distress from a six-item problem list (illness-related, family, psychologic, practical, financial, spiritual effects, or other) (Fig. 91-2).[120,121] Lee et al[122] found that the distress thermometer was a useful tool for screening transplant patients before admission. Pretransplant distress appeared to be highly predictive of distress following transplant and was a feasible marker to use to screen patients for distress.

MANAGEMENT OF PSYCHOSOCIAL PROBLEMS

Interventions for these patients center on the uniqueness of the experience. In the initial phase of the experience, 50% of patients have psychologic distress, including both anxiety and depression.[121] A growing body of literature provides evidence that patients may experience PTSD.[123] Increased length of survival from time of diagnosis has highlighted the need for psychopharmacologic, psychotherapeutic, and cognitive and behaviorally oriented interventions to reduce distress, promote adjustment, and improve quality of life for patients with hematologic malignancies. Cognitive behavioral therapy is a promising intervention that has been used with transplant patients and shown to decrease PTSD symptoms and overall distress.[124] Because of the increasing complexity of patient care, a multidisciplinary approach that includes regular avenues and options for communication about patient management and status updates is imperative. Numerous studies have documented the efficacy of a

Figure 91-2 NATIONAL COMPREHENSIVE CANCER NETWORK (NCCN) DISTRESS MANAGEMENT GUIDELINE DIS-A-DISTRESS THERMOMETER. *(From National Comprehensive Cancer Network:* The National Comprehensive Cancer Network 1.2005 Distress Management, *the complete library of NCCN clinical practice guidelines in oncology (CD-ROM), Jenkintown, Pennsylvania, 2005, National Comprehensive Cancer Network.)*

variety of modalities in managing psychosocial problems for such patients. Problems that can be managed effectively include psychologic distress such as anxiety and depression; sexual dysfunction; body image disturbances; noncompliance, pain, and neurologic complications such as delirium and dementia induced by brain metastasis or treatment; anticipatory and posttreatment nausea and vomiting; anorexia and feeding problems; and marital and family difficulties.

Pharmacologic Interventions

Pharmacotherapy, as an adjunct to one or more of the psychotherapies, can be an important aid in bringing psychologic symptoms under control. For patients with excessive anxiety, factors other than a psychologic state must first be evaluated. Metabolic abnormalities, pain, hypoxia, and drug withdrawal states all can present as anxiety. Many common medications and substances are associated with anxiety and depression. Medications such as steroids and antipsychotics, often used to control nausea, can cause anxiety characterized by agitation and motor restlessness. After medical or drug-induced causes for anxiety are ruled out, an anxiolytic agent is the treatment of choice, except for patients who present with panic episodes, in whom tricyclic antidepressants are most efficacious. Medications are most effective when used at adequate dosages and as standing orders. Use of these medications may assist the patient with participating in psychotherapy, which can provide more lasting control over psychologic symptoms. Anxiety that develops in the context of the terminal stages of cancer often results from hypoxia or an untreated pain syndrome. Intravenous morphine sulfate and oxygen usually are effective palliative treatments. All pharmacologic treatments must be monitored for effectiveness and side effects.

Patients commonly demonstrate transient depressive symptoms at various points in the disease trajectory, particularly during the palliative care period when a hope for cure is not possible. In patients who exhibit prolonged or severe depressive symptoms, a major depressive illness must be considered. Depression can be related to a recurrence of a past depressive disorder or the stress associated with treatment, or it can be a result of the illness process or treatment agents. Antidepressant medications are easily administered and are an effective treatment strategy. Disadvantages include the need for repeated visits to health care clinicians to monitor patient response and adjust the dosage, possible adverse side effects and medical reactions, potential use in suicide attempts, and the need for strict adherence to the medication schedule. Patients should be informed that most antidepressant medications must be taken for 3 to 4 weeks before a significant response is achieved. The clinician must be aware that patients at risk for suicide become more energized with medications and appear to look better long before their depressive feelings and suicidal

thoughts are relieved. Careful monitoring of suicidal ideation should continue for weeks after the patient appears improved.

A diagnosis of major depression in medically ill patients relies heavily on the presence of affective symptoms such as hopelessness, crying spells, and guilt; preoccupation with death or suicide; feelings of diminished self-worth; and loss of pleasure in most activities, such as being with friends and loved ones. The neurovegetative symptoms that usually characterize depression in physically healthy individuals are not good predictors of depression in the medically ill because disease and treatment can also produce these symptoms. A combination of psychotherapy and antidepressant medication often proves useful in treating major depression.[125] Antidepressant medications may take 2 to 6 weeks to produce their desired effects. Patients may need ongoing support, reassurance, and monitoring in the period before the antidepressant effects of medication are achieved. Patients must be monitored closely by a consistent provider during the initiation and modification of psychopharmacologic regimens.

Psychotropic drugs are highly effective for treatment of anxiety, depression, agitation, and confusion in patients with hematologic malignancies.[126] It is beyond the scope of this chapter to include the current medications recommended for common psychiatric disorders. A comprehensive discussion of psychotropic drugs is summarized in the quick pocketbook reference for oncology clinicians.[126] Medications specific for the management of anxiety, depression, and delirium also are presented.[127]

Psychotherapeutic Modalities

"Returning to normal" is a prominent theme and desired goal in the clinical management of patients but is not always possible for patients with hematologic malignancies.[103,128] Survivors of cancer continue to face challenges with long-term physical and psychologic symptoms long after treatment has ended, and data indicate that they report more contact with mental health providers than do people without cancer.[114] The American Society for Blood and Marrow Transplantation released a joint statement recommending screening and preventive practices for long-term survivors of hematopoietic cell transplantation. The recommendation states that "a high level of vigilance for psychologic symptoms should be maintained. Clinical assessment is recommended throughout the recovery period, at 6 months, 1 year and annually thereafter, with mental health professional counseling recommended for those with recognized deficits."[62] The number of intervention studies designed with the hematologic population is limited; however, growing interest in survivorship is changing the research climate in this area.

Support groups can provide a therapeutic experience for patients and family members. Initial evidence suggests that support groups may help reduce health care costs along with depression, mood disturbance, and psychiatric symptoms in patients.[129] Patients often feel alone in their distress and report that sharing a common experience normalizes their feelings, provides an avenue for emotional support, facilitates dialogue to problem solve, and offers opportunities to learn from other patients. Support groups facilitated by professionals such as social workers, nurses, or psychologists can provide a forum for health and psychologic education and provide patients with printed literature and online community-based resources. Sherman et al[41] found that psychoeducational support groups facilitated by professionals were a helpful strategy for patients' post-HSCT psychologic recovery.

Other modalities have been shown to be effective with patients.[103,104] Studies have consistently shown that relaxation training with or without guided imagery or hypnosis may have some benefit with improving quality of life, symptom management, and anxiety and depression management.[128,130,131] It is a skill taught to patients that takes minimal time. It does, however, require that patients be motivated to learn and practice new techniques and a way of coping. Cognitive therapy/reappraisal, problem solving, and stress management training also have been shown to be helpful in the general cancer population.[123,128,132] Fritzsche et al[131] identified that a considerable need for psychotherapeutic treatment of inpatient hematology patients is best handled by mental health professionals. They described a psychosomatic liaison service that provides psychosocial support for patients with hematologic malignancies, including patients going through transplant. The service screened patients for anxiety, depression, poor coping, quality of life, and psychosocial openness for support and provided psychotherapy, relaxation training, or group therapy as interventions. Although all transplant patients received support from the team, 23% of the hematology patients on the general ward received additional psychosocial interventions.

Other evidence-based interventions that have been found to be helpful in the general oncology population include individual and group counseling, family therapy, and music and art therapy. In comparison to patients with solid cancers, there should be a low threshold for referral for psychosocial support for patients and families faced with a hematologic malignancy because the primary treatment is intense and long and associated with sensitivity to potential barriers such as economic constraints, including loss of insurance. It has been estimated that one of six cancer survivors with mental health problems who need services are unable to access those services due to cost.[114] If cost is prohibitive and referral to a psychologist is not feasible, both patients and providers must investigate other potential providers, such as chaplains, art therapists, music therapists, social workers, and psychiatric advanced practice nurses who might be able to see patients as part of their work responsibilities. Other possibilities include online support groups and advocacy organizations, including local wellness communities.

Depending on the nature of the problem, the treatment modality may take the form of individual psychotherapy, group therapy, family therapy, marital therapy, cognitive or behaviorally oriented therapy, or some combination.[10] Increasing evidence supports use of an aerobic exercise program for patients with hematologic malignancies.[133-135] Researchers have concluded that fatigue and loss of physical performance in patients undergoing BMT may improve with exercise.[134] Others have found increased muscle strength with supervised weight bearing and lifting after allogeneic BMT.[135] Table 91-3 outlines the major psychotherapeutic modalities and their advantages, goals, and indications.

FUTURE DIRECTIONS

The psychosocial issues faced by people diagnosed with and treated for hematologic malignancies are influenced by individual, environmental, and disease-related factors. Because involvement in decision making clearly is a positive aspect of current cancer therapies, great care should be taken to ensure that communication is timely, repeated, relevant, and consistent with the patient's needs, tolerance for information, and comprehension. A multidisciplinary approach is necessary to guarantee the communication of timely and essential information to patients and family members. Patients should be given the opportunity to speak with multiple members of the multidisciplinary treatment team and other patients who have experienced similar management and treatment protocols. Care should be taken to provide needed information from a variety of expert perspectives while respecting the unique characteristics, psychosocial profiles, needs, and desires of each individual. In treatment settings with limited resources, every effort should be made to enlist the help and support of providers and services that can assist patients with treatment decisions and their complex management. Referral to community resources and support services after discharge from the hospital often is helpful, even for patients who cope well with initial treatment.[20]

Most patients undergoing cancer treatment, as well as their families, experience expected periods of psychologic turmoil that occur at transition points along the clinical course of cancer. In a small proportion of patients, more severe psychiatric complications may occur, warranting referral to a psychiatric specialist, including psychiatrists, social workers, psychologists, and psychiatric nurses. Screening for ongoing psychiatric problems must become standard care. A variety of psychotherapeutic modalities are useful for helping patients

Table 91-3 Therapeutic Modalities Useful for Patients and Family Members

Modality	Selected Indications	Goals and Advantages	Comments
Individual psychotherapy	Prolonged adverse reactions to diagnosis, treatment, and other aspects of chronic illness (e.g., anxiety, depression)	Supports patients and enhances ability to cope with distressing feelings Short-term therapy; focused and goal directed	Pharmacology and family involvement are useful adjuncts in some cases.
Support groups	Patients desire contact with others who are experiencing chronic illness	Supports patient and enhances coping ability Patients benefit by observing coping strategies of others Usually does not involve a fee	Expands social network of patients with limited support systems
Family and marital therapy	Relationship problems secondary to illness (e.g., family tension, role changes, conflict, sexual problems)	Assists couples with clarifying problems and facilitates solving them together Addresses role changes in the family system	Problems, issues, and concerns about relationships including children can be addressed.
Mind-body therapies, including progressive muscle relaxation, yoga, guided imagery, Reiki, meditation, hypnosis, and biofeedback	Patients desire assistance with control of pain, anxiety, anticipatory and posttreatment nausea and vomiting, fears associated with medical procedures	Increases sense of control and participation in treatment Individualized to meet patient's preferences and circumstances Time limited and goal directed Evaluated in terms of observable changes in symptoms and self-efficacy	Realistic goals should be stated explicitly. (Some patients may view these therapies as a cancer cure.)

work through the expected psychologic responses to cancer as well as more severe responses.[24] Supportive psychotherapeutic measures should be used routinely because they minimize distress and enhance feelings of control and mastery over self and environment. For these reasons alone, their value in the care of patients with cancer is paramount.

Throughout the clinical course of cancer, the patient's relationship with health care providers and the presence of a supportive social network are important factors that can ensure successful management of the many physical and psychosocial demands imposed by a cancer diagnosis and treatment. As scientific inquiry continues to produce vast but sometimes conflicting information regarding etiology and treatment of cancers, concurrent research regarding the psychosocial aspects of hematologic malignancies is crucial. This line of inquiry will, at the very least, assist in promoting psychosocial well-being in patients and family members faced with an extreme and unexpected life crisis. At best, expanding the knowledge base relative to the psychosocial aspects of cancer may provide some "missing links" regarding psychosocial adaptation and quality of life and the impact of cancer on patients' survival. The Institute of Medicine report that recommends that all cancer care should ensure the provision of appropriate psychosocial health services states that at a minimum, patients must be screened for emotional distress and evaluated for additional services.

CHAPTER 92

PAIN MANAGEMENT AND ANTIEMETIC THERAPY IN HEMATOLOGIC DISORDERS

Kathy J. Selvaggi, Bridget Fowler Scullion, Craig D. Blinderman, and Janet L. Abrahm

Relieving the pain of patients who have hematologic disorders requires a multifaceted approach.[1,2] An understanding of the taxonomy of pain, basic pain pathophysiology, and a systematic evaluation of the pain complaint will provide a rational basis for treatment decisions. After the source of the pain has been identified, appropriate nonpharmacologic and pharmacologic therapies can be initiated. The neurosurgical and anesthetic procedures for the management of cancer pain are not discussed in this chapter; those interested in these techniques are referred to several excellent reviews.[1-4]

TAXONOMY OF PAIN

Although there is no one standardized classification system for cancer pain, several systems have been proposed. Cancer pain syndromes, and thus by analogy, pain syndromes in hematologic disorders, may be classified temporally, pathophysiologically, etiologically, according to distinct clinical-anatomical entities, or any combination thereof. It is important to determine both the etiology and inferred pathophysiology in the assessment of the pain complaint because this may suggest the use of specific therapies. Pain can be categorized as *nociceptive* (somatic or visceral), *neuropathic,* or *idiopathic*. Nociceptive pain is pain that is sustained predominantly by tissue injury or inflammation. Nociceptive somatic pain is described as sharp, aching, stabbing, throbbing, or pressure-like. Nociceptive visceral pain is poorly localized and is usually described as crampy pain (e.g., obstruction of hollow viscus) or as aching and stabbing (e.g., pain secondary to splenomegaly). Neuropathic pain is sustained by abnormal somatosensory processing in the peripheral or central nervous system (CNS). Sensations described as "burning," "shocklike," and "electrical" typically suggest neuropathic pain. On physical examination, patients may have allodynia (pain induced by nonpainful stimuli) and hyperalgesia (increased perception of painful stimuli). In the absence of evidence sufficient to label pain as either nociceptive or neuropathic, we may use the term "idiopathic." However, in patients with hematologic disorders, this term should lead to additional workup and a search for an underlying etiology and pathophysiology.

BASIC PAIN PATHOPHYSIOLOGY

Pain is defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage. For a patient to feel pain,[1] a signal arising from a noxious stimulus in the periphery must be transmitted to the centers in the brain that create the experience of pain. After activation of peripheral receptors by chemical, thermal, or mechanical stimuli, the signal passes along unmyelinated A-delta or C fibers and enters the spinal cord via the dorsal root ganglion. Chemicals released at the site of tissue injury mediate or modulate the transmission of the pain signal. Arachidonic acid metabolites, bradykinin, adenosine, serotonin, nitric oxide, prostaglandins, and lipoxygenase products have all been identified as playing a role in initiating or increasing the transmission of the pain signal in peripheral nociceptors.

The dorsal horn of the spinal cord is where the peripheral signals are received and modulated. The excitatory amino acids (e.g., glutamate and aspartate) and neuropeptides (e.g., substance P and calcitonin gene-related peptide [CGRP]) enhance transmission of the peripheral signal.[1] But a complex interaction of other neurotransmitters (i.e., γ-aminobutyric acid [GABA], glycine, adenosine, bombesin, cholecystokinin, dynorphin, enkephalin, neuropeptide-Y, neurotensin, substance P, somatostatin, and vasoactive intestinal peptide) determines whether the signal will proceed up the spinothalamic tract.[1] The signals that are transmitted ascend in one of the two contralateral spinothalamic tracts: the paleospinothalamic tract, which mediates the "suffering" and autonomic reactions to pain, or the neospinothalamic tract, which localizes the pain and records its intensity.[1]

Descending pathways originating in the CNS can inhibit transmission of the pain signal. A modulatory network with major relays in the midbrain periaqueductal grey (PAG) and rostral ventromedial medulla (RVM) exerts control over dorsal horn nociceptive transmission and is the central substrate of opioids—both endogenous and exogenous.[5] This major pain-modulating pathway involves regions of the frontal lobe, amygdala, and hypothalamus, all of which have projections to the PAG. The PAG inhibits spinal nociceptive neurons via connections in the RVM and the dorsolateral pontine tegmentum. The neurotransmitters involved in this and other central inhibitory pathways include serotonin, norepinephrine, cholecystokinin, neurotensin, acetylcholine, cannabinoids, and the endogenous opiates β-endorphin, enkephalin, and dynorphin.[5]

Opiate receptors for endogenous and exogenous opioids are present in the dorsal horn of the spinal cord, in those ventromedial thalamic nuclei that transmit signals from the paleospinothalamic tract, the periaqueductal gray, the periventricular diencephalon, and the amygdala.[5] The analgesic affects of opioids is thought to be attributable to the reduction of neurotransmitter release (e.g., glutamate, substance P, and others) from presynaptic nociceptive fibers, as well as postsynaptic inhibition of neurons transmitting the painful signal to the brain.

The *N*-methyl-D-aspartate (NMDA) receptor at the level of the spinal cord plays an important role in chronic painful states. Chronic pain or long-term opioid therapy may result in activation of the NMDA receptors. Activation of the NMDA receptor initiates intracellular processes that lead to several neuronal plastic changes, which in turn result in enduring increases in neuronal excitability.[6] Antagonists of these receptors (e.g., ketamine and dextromethorphan) may enhance analgesia and reduce the amount of opioid analgesics required. Further studies are necessary to determine the clinical role of NMDA antagonists.

Several reviews have described the diverse pathophysiological processes involved in neuropathic pain.[7] Most neuropathic pain syndromes are the result of peripheral nerve injury. After injury, changes occur at the molecular level, within the nerve itself, and within the spinal cord and brain. At the molecular level, there is upregulation in the expression of both tetrodotoxin-sensitive (TTX-S) and tetrodotoxin-resistant (TTX-R) Na channels. These Na channels are the targets for many of the adjuvant medications used to treat neuropathic pain (e.g., local anesthetics, antiarrhythmics, anticonvulsants, and tricyclic antidepressants [TCAs]).[8] Other cellular components that are thought to play a role in neuropathic pain include TRPV-1 channels, N and P/Q type voltage-gated calcium channels, purine

receptors (P2X), TrkA, proton receptors, and cannabinoid receptors (CB1, CB2).[7] Additional changes take place within the nerve itself. After injury to peripheral nerves, there is a subsequent change in the phenotype of the nerves by de novo gene expression. Both injured and unaffected nerves develop a sensitivity to a number of factors to which they were previously insensitive and respond to subthreshold stimuli. Such sensitization may lead to ectopic and spontaneous activity in tissue nociceptors, perhaps explaining paroxysmal episodes of pain. A host of chemical and inflammatory mediators further alters the gene expression of nerves, leading to increased sensitivity. At the level of the spinal cord, several processes occur that alter the way sensory nerves function, thus maintaining a pathological pain state. These processes can be described as reorganization, sensitization, and disinhibition.[8] Reorganization refers to the phenomenon of new connections being established in the laminae of the spinal cord (e.g., A-beta fibers, which normally transmit light touch) sprout into lamina II of the dorsal horn, replacing C-fibers which transmit nociceptive information to second order neurons. Dorsal horn neurons also become sensitized as a result of repeated firing from peripheral nerve fibers. The release of substance P, CGRP, and other neuropeptides leads to the activation of the NMDA receptor and release of nitric oxide postsynaptically with subsequent excitation of pain transmission neurons (PTNs). Microglia activation also plays a role in sensitization and maintaining pathological pain states. Finally, disinhibition at the level of the spinal cord is thought to be a result of interneuron death in lamina II, downregulation of GABA and opioid receptors, and increased production of cholecystokinin.[8]

EVALUATION OF THE PAIN COMPLAINT

Initial Evaluation

Effective pain management requires a comprehensive assessment of the patient's pain. Pain reports by patients should be believed. The clinical presentation of a patient with chronic pain is very different from that of a patient in acute pain. If a patient does not manifest the common autonomic manifestations of acute pain (e.g., tachycardia, sweating, elevated blood pressure) or facial grimacing, the clinician might doubt that the patient has severe pain. A patient with severe but chronic pain does not manifest these autonomic findings but often is withdrawn, quiet, depressed, or irritable; moves very little spontaneously; and complains of discomfort when moved. When the pain is relieved, these patients often exhibit completely different behaviors, becoming mobile, engaged, and involved with other people. The first component in the assessment is to believe the patient's complaint.

Patient reports of pain are valid, reliable, and reproducible.[1] A variety of assessment tools that can be completed within 5 to 10 minutes are available.[1,9] The pain complaint should be characterized by a number of descriptors, including the pain location, intensity, quality, onset, and duration; location and patterns of radiation; and what relieves or exacerbates the pain and its functional consequences, including how the pain affects the patient's ability to sleep or eat and how it affects physical activity, relationships with others, emotions, and concentration. Most patients with chronic cancer pain also experience periodic flares of pain, or "breakthrough pain."[9] An important subtype of breakthrough pain is "incident pain," which is caused by voluntary activity. The initial evaluation should determine the extent to which the patient has breakthrough pain and if it is provoked by movement (nociceptive) or tends to be paroxysmal in nature (neuropathic). This subjective information, combined with the physical examination and diagnostic studies, may identify a specific pain syndrome and its implied pathophysiology.

In a patient with a hematologic disorder, the cause of pain may be the disease itself, the specific therapy for the disease, diagnostic procedures related to the disease, or unrelated disorders (Table 92-1). Splenomegaly, bone injury (e.g., infarction, infection, hemarthroses, and infiltration), leptomeningeal infiltration, and spinal cord compression frequently accompany hematologic diseases. Chemotherapy and radiation therapy can cause mucositis, typhlitis, hemorrhagic cystitis, and peripheral neuropathy; corticosteroid withdrawal may cause myalgias. Immunosuppression, caused by the diseases themselves or by the therapies used to treat them, may lead to painful infections such as perirectal abscesses, herpetic or candidal esophagitis, and herpes zoster. Patients with sickle cell disease have a number of causes for both acute and chronic pain (Table 92-2).

Table 92-1 Common Pain Syndromes in Hematologic Malignancies

Procedure-Related Pain	
Bone marrow biopsy	
Central catheter placement	
Lumbar puncture headache	
Therapy-Related Pain	
Myalgias (e.g., from corticosteroid withdrawal)	
Myopathy	
Oropharyngeal mucositis	
Osteoporosis	
Peripheral neuropathies (e.g., secondary to chemotherapy agents)	
Postherpetic neuralgia	
Visceral pain syndromes (e.g., typhlitis, hemorrhagic cystitis, enteritis)	
Pain from Hematologic Malignancy	
Pain syndrome	Cause(s)
Bone pain	Bone marrow expansion or infiltration
	Bone infarct or necrosis
	Osteomyelitis
	Compression fracture
	Hemarthrosis
Visceral pain	Tumor involvement
	Splenomegaly
	Lymphadenopathy or lymphadenitis
Headache	Meningeal infiltration, infection
	Brain metastasis or primary tumor
Neuropathic pain	Paraproteins with antimyelin properties
	Amyloid infiltration
	Peripheral nerve compression
	Spinal cord compression

Distress, however, may arise from non-anatomic sources. The pain complaint may represent the patient's only means of expressing nonspecific feelings of distress to the physician. Chapman recognized three categories of this distress: anxiety, arising from fear of disfigurement or of uncontrollable pain, fear of loss of social position or of self-control, or fear of death; anger at the failure of the physicians to provide a cure; and depression from the loss of physical ability, a sense of helplessness, and the impact of financial problems. In addition to these psychological, social, and financial contributions, spiritual concerns may exacerbate any concomitant painful sensations.[10] Alleviating them may significantly reduce distress and decrease the need for pain medications or other interventions.

For a patient whose complaint of pain does not seem to have a straightforward explanation or who has not responded well to the therapeutic maneuvers outlined in this chapter, additional questions may help evaluate the patient's distress. Some patients may deny the extent of their disease and use the complaint of pain to justify their incapacity. For example, when asked: "How would life be different without the pain?" Such patients may give unrealistic assessments of the extent of their abilities, such as, "If only the pain were gone. …" Another question that we have found valuable in this situation is: "What do you think is causing your pain?" The patient may not acknowledge the effects of cancer or its treatment on his or her pain. In addition, the answer may reveal hidden fears, resentments, and even distrust of the physician. Finally, when answering the question: "To what extent do you expect your pain to be relieved?" the

Table 92-2 Classification of Pain Syndromes in Sickle Cell Disease

- Pain secondary to the disease itself
 - Acute pain syndromes
 - Acute chest syndrome
 - Calculus cholecystitis (pigment stones)
 - Hand–foot syndrome (in children)
 - Hepatic crisis
 - Priapism
 - Pulmonary infarction
 - Recurrent acute painful episode
 - Splenic sequestration (in children)
 - Chronic pain syndromes
 - Arthropathies or arthritis
 - Avascular necrosis
 - Chronic osteomyelitis
 - Intractable chronic pain
 - Leg ulcers
 - Neuropathic pain
- Pain secondary to therapy
 - Loose prosthesis (in patients after arthroplasty for avascular necrosis)
 - Opioid withdrawal
 - Postoperative pain
- Pain caused by comorbid conditions

Adapted from Ballas SK. Pain management of sickle cell disease. *Hematol Oncol Clin North Am* 19:785, 2005.

patient may expect that taking one pill each day will provide total relief, but the physician expects that even a multiple-modality pain treatment will relieve only 75% of the pain, thus highlighting the patient's unrealistic expectations of pain treatment.

Sometimes there may be a disparity between the patient's expression of pain and the patient's family or friends' appreciation of the impact of the pain. The following observation may help to begin a conversation around this issue: "You seem to show different feelings about the pain from those your family and friends show. Help me to understand what the pain is like for you and why you think your family and friends feel differently." Patients may come from a cultural background different from the person reporting the pain, and people with cultural differences often report pain very differently.[10] For example, patients from a "stoic" cultural upbringing may not communicate their distress to their spouse; the spouse may then question why the patient needs opioid pain medications (i.e., if the spouse were ill and were in that much pain, he would be sure to talk about it.)

Continued Assessment

A standardized measurement tool, such as a verbal rating scale (VRS) or a visual analog scale (VAS), should be consistently used during follow-up visits.[1,9] These measurements are thought to be more accurate than mere qualitative descriptors, such as: "The pain is better." Using, for example, a scale of 0 (no pain) to 10 (the worst pain one can imagine), a decrease in pain intensity from 10 to 8 indicates that the patient needs a stronger pain medication, but a decrease from 10 to 3 suggests that the current medication regimen is effective. This inference can be confirmed by asking the patient, "Is this level of pain relief acceptable to you?"[1] The ongoing assessment should also pay attention to changes in the phenomenology of the pain, new occurrences of pain, or a change in the location of pain—all of which may suggest progression of disease in the patient with a hematologic disorder.

The successful outcome of pain therapy should be more than simply the lowering of pain intensity scores. Passik and Weinreb developed a useful mnemonic device for the assessment of pain therapy in chronic nonmalignant pain known as the "4 As": analgesia, activities of daily living, adverse events, and aberrant drug-taking behaviors (e.g., repeated dose escalation or noncompliance, hoarding drugs or acquiring drugs from other medical sources). By focusing on these relevant domains in the continued assessment of the pain therapy, the clinician is able to determine if the therapy makes a true difference in the patient's life, stabilizes or improves psychosocial functioning, manages side effects, and provides a means of assessing for aberrant drug behaviors. Ultimately, the goal should be to lower the pain *to a level acceptable to the patient* and to improve the patient's level of functioning.

THERAPY

A major component of pain therapy is an attempt to ameliorate the underlying cause of the pain. Surgery, chemotherapy, radiation therapy, immunosuppression, and antibiotics may all be used. However, the pain can still be treated effectively during diagnostic testing to define the cause, during specific therapy, or after all disease-related therapies are exhausted.

NONPHARMACOLOGIC METHODS OF PAIN MANAGEMENT

Cognitive-Behavioral Interventions

Education and Reassurance

Patients with serious hematologic disorders are often required to undergo extensive diagnostic testing, which can include painful procedures. A rehearsal of the planned test or procedure, including a discussion (or view) of the appearance of the room and the length of time to be spent in the test apparatus, can minimize the patient's anxiety. Such explanations, offered preoperatively, lessen the need for postoperative medication and shorten the patient's hospital stay. If conscious sedation is not planned, a pleasant distraction may be helpful to divert attention from certain procedures (e.g., bone marrow aspiration or biopsy) that take place in the physician's office or in the patient's room. For example, the physician might encourage the patient to bring in a CD or MP3 player with earphones so the patient can listen to a favorite piece of music or a book on tape while the procedure is taking place. Patients can also dissociate themselves[10] from the procedure by concentrating on pleasant memories and thereby diminishing the painfulness of the procedure.

Hypnosis

Hypnosis can be a useful adjunct in the management of pain, including for patients undergoing painful procedures.[10] The hypnotic trance, a state of heightened and focused concentration, allows one to manipulate the perception of pain and diminish sleeplessness, anxiety, and anticipation of discomfort. Hypnotic training of patients with sickle cell anemia or hemophilia decreases the frequency and pain intensity of painful crises or bleeding episodes, respectively. In a controlled trial comparing hypnosis with cognitive-behavioral therapy in relieving mucositis after a bone marrow transplant, patients using hypnosis reported a significant reduction in pain control compared with patients who used cognitive-behavioral techniques.[11]

In the absence of a formal hypnotic induction, words used by a practitioner to describe procedures are very important. For example, the suggestion that skin coolness and numbness will persist after application of an alcohol swab may markedly diminish the discomfort of starting an intravenous line. Using the phrase: "You will feel something; I'm not sure what you will feel because everyone feels this a little differently" in place of "This is going to hurt a lot!" gives the patient permission to alter the sensation and may also diminish the experience of pain.

Cognitive-Behavioral Techniques and Counseling

The cognitive-behavioral approach addresses a number of psychosocial and behavioral factors that contribute to patients' experience of pain.[9,10] These techniques have demonstrated clinical utility for patients with a wide range of chronic pain syndromes. Psychological counseling as part of a multidisciplinary approach to pain treatment provides education, support, and skill development for patients with pain. It can improve patients' abilities to communicate their pain to health care personnel and may be effective in overcoming anxiety and depression. Spiritual counseling may help patients who have lost hope, can find no meaning in their lives, or believe they are being punished or have been forsaken by God.[10] They may interpret their pain in light of these feelings. Through counseling, they can regain a sense of worth and belonging. As they recast the pain in its true light, its intensity is often diminished.

Cutaneous Techniques

Acupuncture, massage, vibration, and applying cold or heat to the skin over injured areas are often very effective. Cold wraps, ice packs, or cold massage using a cup filled with water that has frozen into a solid piece of ice relieve the pain of muscles that are in spasm from nerve injury. Heat from heating pads, hot wraps, or paraffin treatments can soothe injured joints but should not be used over areas of vascular insufficiency. Transcutaneous electrical nerve stimulation (TENS) devices are indicated for patients with dermatomal pain, such as postherpetic neuralgia or radiculopathy from spinal cord compression.[10] For optimal effect, a physiatrist or physical therapist familiar with the device should train the patient in its use. The efficacy of TENS therapy for patients with cancer pain remains controversial.

EMLA, a cream containing two topical anesthetics (2.5% lidocaine and 2.5% prilocaine) is used, especially in children, to decrease the pain of superficial cutaneous procedures (e.g., venous cannulation or skin anesthesia before lumbar puncture, bone marrow aspiration, or biopsy).[10] In adults, it is used before access of implanted vascular access devices or CNS ports. To achieve anesthesia, the EMLA cream must be applied 1 to 1.5 hours before the planned procedure in a mound under a semipermeable dressing such as Opsite or Tegaderm. When EMLA is used as directed, methemoglobinemia has not been a problem even in infants as young as 3 months old. Skin blanching occurs, sometimes exceeding or equaling the frequency of that found with placebo moisturizing cream placed under the occlusive dressing. ELA-Max, a cream containing 4% lidocaine, is available over the counter and is an alternative to EMLA cream. Because it does not contain prilocaine, there is no risk of methemoglobinemia.

Lidocaine patches can be used over areas of hyperesthesia, as can occur in patients with postherpetic neuralgia or nerve entrapment by vertebral body collapse.[10] The patch is applied to the affected area for no more than 12 consecutive hours a day and can be cut to size. Use should be avoided over areas of broken skin and in patients undergoing radiation therapy. Extended application of lidocaine patches has been safely applied for up to 24 hours/day for up to 4 days with minimal systemic absorption in healthy volunteers and in postherpetic neuralgia patients.

Radiation Therapy

Radiation therapy is commonly used in the management of painful bone lesions, spinal cord compression, bulky lymphadenopathy, and symptomatic splenomegaly in patients with hematologic malignancies.[10,12] Radiotherapy is the treatment of choice for local metastatic bone pain in most situations, although patients with underlying pathologic fractures may require surgical fixation before radiotherapy. Randomized trials have shown that single-fraction radiotherapy is as effective as multifraction radiotherapy in relieving pain caused by metastases. However, there are higher rates of retreatment, and single-fraction radiotherapy may not prevent pathological fractures or spinal cord compression.[12] In patients with poor performance status or a short life expectancy, a single dose (8 Gy) of radiation or a hypofractionated course (20 Gy/5 fractions) may be preferable and less burdensome.

Vertebroplasty and Kyphoplasty

Vertebroplasty and kyphoplasty are both minimally invasive techniques used to stabilize vertebral compression fractures and reduce pain. Vertebroplasty is a procedure in which bone cement, usually polymethylmethacrylate, is injected into the vertebral body. With kyphoplasty, a balloon is first inserted into the vertebral body followed by inflation and then deflation before cement is added. Balloon kyphoplasty has been shown to stabilize pathological vertebral fractures caused by multiple myeloma and significantly reduce pain.[13]

Anesthetic Techniques

Trigger-point injections, nerve blocks, and neurolytic procedures are useful for acute and chronic localized pain. After excisional biopsy of an axillary lymph node, for example, a burning, constricting pain in the posterior arm and chest wall may develop; this pain is often promptly relieved by trigger-point injection.

Lymphoma or myeloma may involve the spine and lead to vertebral collapse or pain from progressive disease that is refractory to antineoplastic therapy. Such pain is often particularly difficult to manage. Insertion of temporary or permanent indwelling epidural or intrathecal catheters to deliver opioids, local anesthetic agents, clonidine, or combinations of these and other agents can be very effective, especially in relieving lower thoracic or lumbar spine pain, as well as pelvic and lower extremity pain.[14] Reviews of the indications for and techniques of the anesthetic and neurolytic procedures are available.[4]

PHARMACOTHERAPY

Drugs useful for pain relief include nonopioid analgesics, opioids, and adjuvant analgesics. Most patients require a combination of medications for optimal pain relief (Fig. 92-1).

Nonopioid Analgesics

Nonopioid analgesics should be given to patients with mild to moderate pain.[1,9] Aspirin and nonsteroidal antiinflammatory drugs (NSAIDs), including cyclooxygenase-2 (COX-2) inhibitors, are especially useful as antiinflammatory agents because they decrease local prostaglandin release through the inhibition of COX (though the mechanisms for their analgesic properties are not as clear).[15] Acetaminophen is an effective analgesic but only a weak antiinflammatory agent. Daily intake of acetaminophen should not exceed 4 g because of the potential hepatic toxicity (see box on Management of Severe Pain). It is important to prescribe an adequate dose of acetaminophen or NSAID at regular intervals, switching to another nonopioid analgesic only when maximal doses of the first have become ineffective.[15]

Ketorolac tromethamine (Toradol) is an NSAID of particular value in relieving moderate to severe acute pain.[16] A parenteral dose of 30 mg of ketorolac equals the pain-relieving potency of a parenteral dose of 15 mg of morphine, and acute toxicity is minimal if the total daily dose is under 100 mg. Oral ketorolac is considered less potent. Ketorolac has all of the side effects of the NSAIDs and is not recommended for use beyond 5 days because of an increased risk of renal toxicity. If that degree of pain relief is needed chronically, an opioid agent should be substituted.

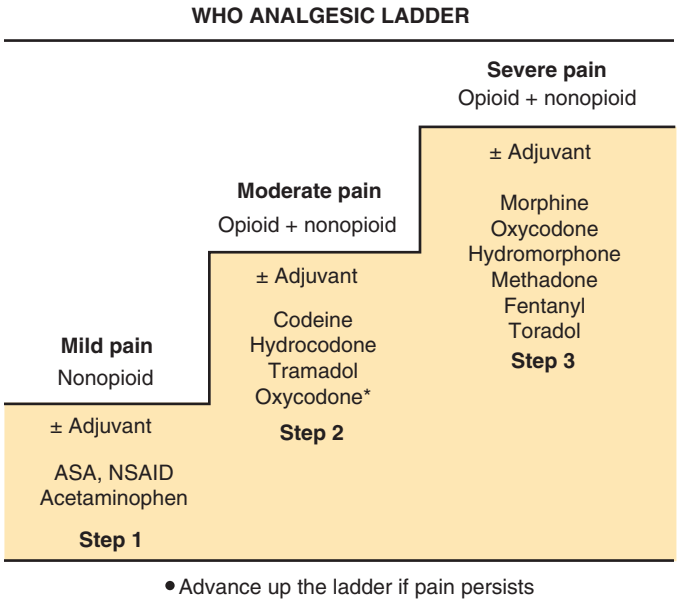

Figure 92-1 STRATEGY FOR PHARMACOLOGIC MANAGEMENT OF PAIN USING THE WORLD HEALTH ORGANIZATION (WHO) ANALGESIC LADDER. Multiagent therapy is usually required for optimal pain management. Patients with mild pain should be started on a nonopioid analgesic, and those with moderate pain should be started on a step 2 opioid. Many patients can benefit from the addition of a nonopioid to the opioid (e.g., for bone pain) or an adjuvant agent to the opioid (e.g., for neuropathic pain). If this combination does not produce adequate relief or the patient presents with severe pain, step 3 opioids should be begun initially. Toradol (Ketorolac) is a nonsteroidal antiinflammatory drug (NSAID) with the pain-relieving potency of a step 3 opioid. Many patients can benefit from the addition of nonopioid analgesics or adjuvants, if indicated. *ASA,* Aspirin; *, oxycodone in combination with products.

Because the NSAIDs can cause renal insufficiency in a significant number of patients, renal function should be assessed 1 or 2 weeks after initiation of any of these agents. NSAIDs should be used with caution in patients with a history of aspirin allergy or asthma because they can precipitate bronchospasm in as many as 20%.[15] Significant edema can occur in patients with cirrhosis or congestive heart failure.[15] The relatively selective COX-2 inhibitors, such as meloxicam, celecoxib, and nabumetone, should not, and apparently do not, cause gastrointestinal side effects with the same frequency as nonselective NSAIDs. If NSAIDs are required in patients with a history of significant gastritis or ulcer disease or who are older than 70 years, COX-2 inhibitors or a concomitant proton pump inhibitor should be considered. Cardiotoxicity is well described in the literature for COX-2 selective inhibitors.[17] Recently, the cardiac risk associated with traditional NSAIDs has been questioned. In a meta-analysis that included naproxen, ibuprofen, diclofenac, and several COX-2 specific inhibitors, ibuprofen and diclofenac demonstrated an increased risk of stroke. Diclofenac was also associated with an increased risk of cardiovascular death. Naproxen was not noted to have risk elevations.[17] The nonopioid analgesics should be continued in appropriate cases when opioid analgesics are added because they can potentiate the pain-relieving effect of the opioid (see Fig. 92-1).[1,9] However, when aspirin or acetaminophen is included in a fixed drug combination (e.g., Percodan, Percocet), toxicities may develop if the patient takes the pills more often than the prescription indicates. The metabolism of salicylates is limited by the capacity of the hepatic microsomal system.[10] After that is saturated, salicylate levels are dependent on renal clearance. Small increases in maintenance doses can lead to serious salicylism. Patients with low albumin levels or acid urine are particularly susceptible to the development of salicylate toxicity.

Management of Severe Pain

Opioid therapy is the cornerstone of management of patients presenting with severe pain. Our practice is to begin with reassurance of patients and their families. We tell them that to relieve the pain as quickly as possible, we will initiate the use of intravenous opioid medications immediately but that we will begin oral pain medication as soon as the pain is well controlled. Without this explanation, patients have misinterpreted a "morphine drip" as an indication that they were considered terminal.

The starting dose is calculated from the patient's current opioid dose (10% of their 24-hour opioid requirement) or weight (e.g., 0.05 mg/kg/hr of morphine). After the opioid bolus dose is administered, the patient should be monitored continuously during dose titration. If the patient was on standing opioid medication, the medication is continued when possible or converted to a continuous infusion if necessary. Pain is reassessed 20 minutes after the patient receives a bolus dose. If the pain remains severe (7, 8, or 9 of 10), a subsequent bolus dose is administered at double the dose. If the pain has decreased to moderate (4, 5, or 6), another bolus at the same dose as the immediately previous dose is used. If the pain score is below 4, the patient is carefully monitored. At 4 to 8 hours, either a continuous infusion is begun or the ongoing infusion rate is adjusted upward based on the amount of opioid taken as boluses during that period. There is no maximal opioid dose; we give whatever is required to relieve the pain. If the patient falls asleep, this is usually an indication that pain relief has been achieved, not that the dose should be lowered. We lower the dose if the respiratory rate falls to below 10 to 12 breaths/min or if there are signs or symptoms of neurotoxicity (e.g., myoclonus).

Agents to prevent side effects are begun along with the opioid. All patients are given a stool softener and an irritant agent such as senna (one or two tablets orally daily to twice daily, up to a maximum of 8 pills per day). If a more laxative effect is needed, lactulose (15-30 mL) or polyethylene glycol (17 g) is added. In opioid-naive patients, prochlorperazine (Compazine 10 mg taken orally two or three times daily) is ordered as needed to treat nausea. In patients with bone or nerve pain, appropriate adjuvants are added.

When pain relief is adequate, the patient is converted to an equivalent dose of oral or transdermal opioid. If morphine is used, for example, the patient will need three times the parenteral dose that was effective (see box on Relative Potencies of Commonly Used Opioids). For example, a patient who requires 10 mg of morphine per hour (i.e., 240 mg/24 hours given intravenously) will need 720 mg/day of the oral sustained-release agent (240 mg every 8 hours). This can also be given orally as 360 mg every 12 hours. Two hours after the long-acting oral opioid is begun, the drip is discontinued. Short-acting immediate-release morphine should be available for rescue dosing at 10% of the total daily dose. For this patient, 60 to 90 mg every 3 to 4 hours is recommended. If the amount of opioid taken as a rescue dose is significant (>25% of the daily dose) for 1 or 2 days, the total dose of long-acting agent is adjusted upward accordingly.

Tramadol, which both weakly inhibits norepinephrine and serotonin reuptake and weakly binds to μ-opioid receptors and has opioid-like side effects but is not an opioid, also relieves mild to moderate pain. A dose of 100 mg is more effective than 60 mg of codeine. Tapentadol also had both μ-receptor agonism and norepinephrine reuptake inhibition. Studied in moderate to severe acute postoperative pain, osteoarthritis and low back pain, doses of 50 to 100 mg every 4 to 6 hours are comparable to oxycodone 10 to 15 mg every 4 to 6 hours with less nausea, vomiting, and constipation.

Opioid Analgesics

Patient Education

Opioid analgesics are the mainstay of therapy for moderate to severe pain of malignant or nonmalignant origin. To ensure patient compliance with an opioid prescription, education of members of the health care team, the patient, and the family is often required to dispel the many misconceptions associated with opioid therapy.[10] Even physicians who are cancer specialists may hesitate to prescribe opioids as needed for patients with severe pain.

Fear of addiction is a common cause of inadequate prescribing of opioids and a barrier to their acceptance by patients.[10] Patient adherence can be improved by providing a full explanation of the differences between addiction and physical dependence along with reassurance that research has repeatedly indicated that patients with malignancies who take opioids do not become addicts.[10] Patients may also fear that if they take opioid medications for moderate pain, the medications will no longer be effective if more severe pain occurs. Because this fear, if unexpressed, can lead to undertreatment, the topic should be addressed even if the patient does not raise the question. A functional goal of therapy, such as returning to a favorite hobby or reinstituting normal activities of everyday life, may enable the patient and the family to accept the opioid. Misconceptions about religious teachings may prevent health care personnel, patients, and their families from giving or accepting adequate pain medication. Catholics, for example, may not be aware of the church's position, as stated in the current catechism, that opioids may be used at the approach of death even if their use ultimately shortens the patient's life. The church does not consider this use of pain medication to be a means of suicide or euthanasia.[10]

Practical Considerations When Using Opioids

Drugs with short half-lives should be used for "rescue doses" given for incident pain (i.e., pain with movement) and for between-dose pain exacerbations often referred to as "breakthrough pain." The dose of the rescue medication should be 10% of the total 24-hour dose.[18] For example, if a patient is receiving 300 mg of oral sustained-release morphine twice each day, the rescue dose should be 10% of 600 mg, which is 60 mg of short-acting morphine. Agents with short half-lives should also be used in elderly patients and in patients with impaired renal or hepatic function.[10] For patients with a history of drug abuse, agents with longer half-lives, such as methadone, are preferred.

There is considerable variability with respect to the side effect profile of the various opioids in each patient. Therefore, it is often useful to switch to another agent if a patient is experiencing dose-limiting side effects with the initial opioid chosen. If the patient receiving morphine experiences disabling nausea, the substitution of oxycodone at an equianalgesic dose, for example, should be considered (see box on Relative Potencies of Commonly Used Opioids). Because of incomplete cross-tolerance, the initial dose for patients taking higher doses of opioids should be only half to two-thirds of the calculated equianalgesic dose.[18] In the same patient taking morphine (600 mg/day taken orally), oxycodone should begin at 200 to 300 mg/day (i.e., half or two-thirds of the 400-mg dose that would be equianalgesic). The short-acting rescue medication (20 or 30 mg of oxycodone) can provide relief if this initial dose does not prove adequate.

Although methadone is not a new drug, it is increasingly used for patients with moderate to severe pain. It is by far the least expensive of the opioids; can be given by the oral, rectal, intravenous, or epidural routes; and has particular usefulness in patients with neuropathic pain.[10] Methadone is structurally unrelated to morphine and fentanyl and can be used in the rare case of true allergy to these. It is also helpful when patients have neurotoxic side effects of the high doses of other opioids that are often needed to control severe neuropathic pain. Methadone is an opioid receptor agonist and a presynaptic inhibitor of NMDA.[19] Patients with neuropathic pain and patients taking opioids chronically have increased levels of NMDA receptors in the dorsal horn of the spinal cord. NMDA antagonizes the activity of the opiate receptors. Blocking the NMDA receptors therefore enhances the analgesic effect of externally administered opioids. Ketamine, a pure NMDA antagonist, similarly enhances opioid efficacy but is associated with more cognitive side effects than methadone.

Choice of Medication

Because a wide variety of medications are available, pharmacokinetic considerations and side effect profiles should be considered when choosing opioid agents. Intermittent moderate to severe pain lasting hours to several days is amenable to oral analgesics with short half-lives (3-4 hours) with appropriate potency (e.g., immediate-release oxycodone, morphine, hydromorphone [Dilaudid], or oxymorphone [Opana] when available). Severe pain of relatively constant intensity should be treated with oral sustained-release morphine or oxycodone taken every 8 or 12 hours,[1,9] hydromorphone (Exalgo) taken every 24 hours or oxymorphone (Opana ER) taken every 12 hours, methadone taken every 8 hours, or transdermal fentanyl renewed every 48 to 72 hours. Twelve- to 24-hour formulations of oral morphine (e.g., Kadian, Avinza) are available; for patients unable to take pills, the capsule can be opened and the pellets sprinkled on food or suspended in water and given through a feeding tube[10] (see boxes on Relative Potencies of Commonly Used Opioids and Choice of Medication).

Relative Potencies of Commonly Used Opioids

Drug	*Epidural*	*SC or IV (mg)*	*PO (mg)*
Morphine	1	10	30
Codeine		130	200
Oxycodone		N/A	20
Hydromorphone	0.15	1.5	7.5
Methadone*		*	
Oxymorphone		1	10
Levorphanol		2	4
Fentanyl		0.1	N/A
Meperidine (Demerol)†		75	300

IV, Intravenous; *N/A,* not applicable; *PO,* oral; *SC,* subcutaneous.
*Methadone is approximately half as potent orally as it is intravenously. It is usually not given SC because of local irritation. Standard equianalgesic tables do not reflect methadone's potency when used in repeated doses.
†Not recommended for patients with chronic pain.

Conversions Between the Transdermal Fentanyl Patch and Morphine

	Morphine (mg/24 hr)	
Fentanyl (mcg/hr)	*Oral*	*IM or IV*
25	50	17
50	100	33
75	150	50
100	200	67
125	250	83
150	300	100

Data from: Miaskowski C, Cleary J, Burney R, et al: *Guideline for the management of cancer pain in adults and children, APS clinical practice guidelines series, No.3.* Glenview, Ill, 2005, American Pain Society.
IM, Intramuscular; *IV,* intravenous.

Methadone interacts with inducers and inhibitors of the cytochrome P450 system. It is extensively metabolized by CYP1A2, CYP3A4, and CYP2D6; the first two are induced by a number of drugs and other substances (e.g., cigarette smoke), and the last enzyme has a genetic polymorphism. Drug levels of desipramine and zidovudine increase when patients are receiving methadone. Drugs that lower the levels of methadone include phenytoin (by 50%), phenobarbital, carbamazepine, rifampicin, and risperidone, each of which has precipitated withdrawal symptoms.[19] Drugs that raise the serum methadone levels include ketoconazole, fluconazole, fluoxetine and fluvoxamine. The selective serotonin reuptake inhibitors (SSRIs) (except venlafaxine) may raise methadone levels in CYP2D6 rapid metabolizers.

Methadone can cause prolongation of the QT interval. A mean methadone dose of 400 mg/day (standard deviation, 283 mg) was found in 17 patients with torsades de pointes. In an evaluation of reports of methadone-related adverse events to the U.S. Food and Drug Administration (FDA), approximately 1% of the greater than 5000 reports were of QT prolongation or torsades de pointes. The median dose was 345 mg with a range of 29 mg to 1680 mg. Drugs that also prolong the QT interval, such as metoclopramide and olanzapine, should be used with caution in patients receiving significant doses of methadone. Gabapentin, the drug used most often as a neuropathic pain adjuvant, does not interact with methadone metabolism.

Other difficulties with using methadone lie in its variable and long biologic half-life and the controversy about its equianalgesic dosing range. Some studies have reported that the equianalgesic dose of morphine to methadone varies as the dose of morphine increases.[10] Dose ratios vary from 4:1 at morphine doses of 30 to 90 mg, to 6:1 at 90 to 300, and to 8:1 at doses of more than 300 mg of morphine. Other studies report a ratio of 20:1 for doses of oral morphine equivalents greater than 1000 mg. Some physicians advise a 3-day conversion to methadone. The first day, the dose of the old opioid is reduced by one-third, and one-third of the calculated dose of methadone is given; the second day, the dose of the remaining opioid is reduced by half, and the dose of methadone is only increased if the patient is experiencing moderate to severe pain; the third day, the old opioid is discontinued, and the standing dose of methadone is adjusted to reflect the rescue doses.[19] When converting patients directly from intravenous fentanyl to intravenous methadone, a conversion ratio of 25 μg/hr of fentanyl to 0.1 mg/hr of methadone has been found in a pilot study to be a safe and effective initial infusion rate.

A new opioid to the U.S. market that is now available in both extended release and immediate release is oxymorphone. Oxymorphone extended release has been found to provide safe and effective pain relief for cancer pain.[20] Oxymorphone extended release is dosed twice daily and is about twice as potent as oxycodone.[21]

Levorphanol, which is chemically similar to dextromethorphan (an NMDA antagonist and cough suppressant), is a potent opioid that may be considered for patients with severe cancer pain. It was originally synthesized as an alternative to morphine more than 40 years ago. It has a greater potency than morphine, approximately five times as potent in its oral formulation. Analgesia is achieved through its agonistic activity at μ, δ, and κ opioid receptors, as well as by its antagonism of NMDA receptors. Levorphanol can be given orally, intravenously, and subcutaneously.

Buprenorphine has long been used to treat patients with addiction as an alternative to methadone. The new buprenorphine patch has been found to be effective in patients with cancer and noncancer pain. Postmarketing surveillance has indicated that 81% of patients achieve good or very good pain relief and about 50% of patients did not require additional medications for breakthrough pain.

Meperidine is eight to 10 times less potent than morphine and has a short duration of action, approximately 2 to 3 hours. Normeperidine, an active metabolite, which induces dysphoria, is excitatory to the CNS and can cause agitation, tremors, myoclonus, and seizures, especially in high doses, with prolonged use, or in renal failure.[10] Normeperidine has a half-life of 13 to 24 hours, which can lengthen with renal failure. The seizure incidence is further increased if the opioid antagonist naloxone (Narcan) must be given. Therefore, meperidine is not recommended for use in patients with long-lasting moderate to severe pain.[1,9]

Routes of Delivery

Opioids can be delivered noninvasively (orally, rectally, transmucosally, or transdermally) or invasively (subcutaneously, intravenously, or by spinal infusion). For patients switched from one route to another such as oral or rectal to parenteral or spinal medication or vice versa the dose must be converted accordingly to avoid overdose or undertreatment (see box on Relative Potencies of Commonly Used Opioids).

Oral Route

Most patients can achieve excellent pain relief with short-acting and/or sustained-release oral opioid preparations. The typical onset of short-acting opioids via the oral route is 45 minutes to 1 hour with a typical duration of action around 3 to 4 hours. When tablets and capsules are not feasible, many liquid forms are available in various concentrations. Some solutions do contain alcohol, which can be irritating to patients with oral lesions.

Rectal Route

Rectal opioids (i.e., morphine, oxymorphone, and hydromorphone) replace subcutaneous injections in patients who are suddenly unable to take oral medications. They have about the same potency and half-life as orally administered agents[10] and must therefore be administered frequently. Oxycodone has been shown to have a similar mean bioavailability but with a large interpatient variability but longer duration of activity (8 hours). Although not approved by the FDA, in single-dose bioavailability studies of sustained-release morphine preparations, despite delayed absorption from the rectal route, total morphine absorption over 24 hours was equivalent, whether the drug was given orally or rectally.[10]

Transdermal Route

The transdermal fentanyl patch delivers the lipophilic fentanyl into the fat-containing areas of the skin. The drug diffuses continuously from the patch's reservoir through a rate-controlling membrane and is absorbed from the skin depot into the bloodstream, where it is rapidly metabolized[10]. The onset of pain relief is delayed about 12 hours, and a relatively constant plasma concentration of fentanyl is not reached until about 14 to 20 hours after the initial patch is placed.[10] Liberal rescue medication must therefore be provided during the first 24 hours of use of the patch. Similarly, if a patient develops signs of fentanyl overdose, naloxone (Narcan) must be given until the skin reservoir has become depleted. About 50% of the drug is still present 24 hours after patch removal. Converting patients from oral or parenteral medication to the patch is easily accomplished[10] (see box on Relative Potencies of Commonly Used Opioids). A new patch is applied every 72 hours, although up to 25% of patients require a new patch every 48 hours.

The transdermal system is an effective method of delivering pain relief for patients with a stable level of chronic moderate to severe pain, no oral route available, or no desire to take pills. Side effects include those caused by the contact adhesive along with those commonly associated with other opioids, but they may be better tolerated than those caused by morphine.

The transdermal system should not be used in patients with sepsis, those experiencing acute pain, those with markedly fluctuating opioid requirements, cachectic patients, or individuals with significant dermatologic insults (i.e., skin graft-versus-host-disease [GVHD] or diffuse varicella). When the patient's temperature rises to 40°C, drug absorption from the skin can increase by as much as 35%. If hepatic function is impaired or sepsis or shock develops and blood flow to

the liver decreases, plasma concentrations may rise sharply. Patients with cachexia lack the subcutaneous tissue necessary for formation of a drug reservoir. Lower doses may also be required in elderly patients and in those with respiratory insufficiency.

Transmucosal Route

Transmucosally administered fentanyl induces rapid analgesia with a short duration of effect (≈1 hour) and is an effective treatment in the management of breakthrough pain.[22] Oral transmucosal fentanyl citrate (Actiq), fentanyl buccal tablet (Fentora), fentanyl buccal soluble film (Onsolis), and fentanyl sublingual tablets (Abstral) as well as a fentanyl nasal spray (Ladanza) are the available transmucosal fentanyl products. They have been found to be both efficacious and safe in the treatment of cancer-related breakthrough pain.

Subcutaneous and Intravenous Routes

Subcutaneous or intravenous administration of opioids can provide pain relief in the shortest amount of time with a minimum of oversedation. The drugs can be delivered by portable infusion pump that is initiated or continued in the home.[10] Guidelines for their use are available. Patient-controlled analgesia (PCA) systems for subcutaneous or intravenous drug delivery have the advantage of responding to the individual patient's threshold for pain while eliminating delays when nurses must administer supplemental medication. The pumps can administer a continuous fixed infusion of the opioid chosen and allow the patient to self-administer boluses of additional medication at frequencies chosen by the physician. By recording the additional amounts of self-administered medication, the devices also facilitate the adjustment of the continuous dose required for pain relief.

Spinal Route

Epidural or intrathecal opioid infusions, which may include the option of PCA, can be helpful for select patients. The infused opioids block pain transmission by binding to receptors in the dorsal horn of the spinal cord. Because the drug is being infused in close proximity to the receptors, only a small amount of opioid is needed, and the systemic side effects are reduced. Problems with this delivery system in patients who are not opioid naive include pruritus, respiratory depression, and sedation. If tolerance to the opioid develops and higher doses are required for relief, the incidence of side effects may approach that of systemically administered opioids. Addition of local anesthetic or α-adrenergic agent (e.g., clonidine) or other agents[14] to the epidural opioid infusion allows for fairly rapid lowering of the opioid concentration and reestablishing opioid sensitivity but can cause hypotension.[23]

Adjuvant Analgesics

Adjuvant analgesics are a diverse class of medications, which typically have indications for conditions other than pain. They have analgesic properties and are often used when an opioid regimen alone is unable to provide sufficient analgesia or is associated with dose-limiting side effects.

Neuropathic Pain

Adjuvant agents for patients with neuropathic pain include anticonvulsants, antidepressants, α_2-adrenergic agonists, corticosteroids, topical agents, GABA agonists, and NMDA receptor antagonists.[1,9,10,24] However, the analgesic antidepressants and anticonvulsants are typically preferred for treating neuropathic pain secondary to cancer.[25]

The anticonvulsants gabapentin (Neurontin) and pregabalin (Lyrica) have the fewest side effects and are very effective for patients with neuropathic pain from tumor, peripheral neuropathy from tumor or treatment, and postherpetic neuralgia.[24] Despite their names, they have no effect on GABA but rather bind to the α-2-delta subunit of the N-type calcium channels in neurons within the dorsal horn, thus inhibiting calcium influx and diminishing neuronal hyperactivity. To minimize sedation, doses should be low at first (e.g., gabapentin 100 mg three times daily or 300 mg at bedtime; pregabalin 50 mg twice a day) and should be increased as tolerated every 3 to 5 days until analgesia is achieved. The effective dose of gabapentin varies between 900 and 3600 mg/day in divided doses and that of pregabalin is 150 to 300 mg twice a day. The pharmacokinetics of gabapentin are unique in that it has a ceiling effect related to a saturable transport mechanism in the gut, such that the effects of this drug may plateau during dose escalation.[25] The most common dose-limiting side effect is sedation. Gabapentin and pregabalin need to be renally dosed in patients with decreased creatinine clearance. Peripheral edema related to gabapentin or pregabalin may require diuretics. Pregabalin's gastrointestinal absorption is proportional to the dose throughout the effective dose range, making titration simpler. Other, generally less effective anticonvulsants used for neuropathic adjuvants include phenytoin, carbamazepine, lamotrigine, topiramate, and tiagabine.

The TCAs (e.g., amitriptyline, nortriptyline) are effective agents for neuropathic pain.[10] The TCAs, when used as adjuvant analgesics, are effective faster and at lower doses than when they are used as antidepressants (e.g., amitriptyline is effective within 2-3 days at 50-100 mg/day). However, because of their anticholinergic side effects, they should be started at doses of 10 to 25 mg at bedtime and used with caution in elderly patients and in patients who have cardiac conduction abnormalities or bladder outlet obstruction. Combination therapy with gabapentin and nortriptyline has been shown to be more effective than either drug alone in patients with diabetic neuropathy and postherpetic neuralgia.[26]

Selective serotonin and norepinephrine reuptake inhibitors (SSNRIs; e.g., venlafaxine and duloxetine) have been shown to be analgesic for a number of neuropathic pain syndromes. There is less evidence supporting the use of SSRIs for neuropathic pain.

Corticosteroids given epidurally, intravenously, or orally are useful as antineoplastics (e.g., in leukemia, lymphoma, and myeloma) and can also provide nonspecific relief for patients with spinal cord compression and plexus infiltrations. Doses of 16 to 100 mg of dexamethasone are needed to reduce vasogenic edema in spinal cord compression,[10] but lesser doses (6-20 mg/day) can be helpful in patients with plexus injuries. Patients must be monitored for the development of oral or esophageal candidiasis and steroid-induced delirium.

Bone Pain

Adjuvants for bone pain include NSAIDs, corticosteroids, bisphosphonates, RANK-L inhibitors (e.g., denosumab), and the radiopharmaceuticals strontium chloride (89Sr) and samarium153-lexidronan.[10] Multiple studies have demonstrated the efficacy of bisphosphonates in reducing skeletal complications and pain from bone metastases.[10] Pamidronate and zoledronate are recommended for patients with multiple myeloma and other hematologic malignancies with painful bone lesions. Calcium and sometimes vitamin D supplementation (especially for denosumab) are often needed.[27] Also, the long-term use of bisphosphonates is associated with a small but meaningful risk of osteonecrosis of the jaw.[27] The limitations of radiopharmaceuticals include cost and cytopenias.[10] Given the limited evidence available, a recent Cochrane review did not support the use of calcitonin for control of pain from bone metastases.

Management of Opioid-Related Side Effects

Sedation

The addition of 2.5 to 7.5 mg of dextroamphetamine or methylphenidate[10] (taken orally twice daily) has been shown to reduce

opioid-induced sedation and at times allow for escalation of opioid doses without sedation. These medications also improve cognitive function and symptoms of depression. Methylphenidate may also enhance the analgesic effects of opioids.[10] They should be avoided in patients with anxiety, moderate to severe hypertension, agitation, thyrotoxicosis, tachyarrhythmias, severe angina pectoris, and closed-angle glaucoma. Modafinil (Provigil), a novel psychostimulant with a mechanism of action different than the amphetamine derivatives, which is approved for narcolepsy and fatigue related to multiple sclerosis, has also been found to be effective for opioid-related sedation.[10]

Constipation

Constipation is the most common opioid-induced side effect.[9] Laxatives should therefore be given routinely, not on an as-needed (PRN) basis,[1,9,10] to patients treated with any of the drugs listed in the box on Relative Potencies of Commonly Used Opioids. Detailed bowel preparation recommendations can be found, but no regimen has been studied in a controlled fashion. Commonly used stool softeners and stimulants include docusate sodium, senna, lactulose, and polyethylene glycol. A combination of a stool softener and laxative seems to be a rational choice for patients taking chronic opioids (e.g., docusate sodium with senna). Promotility agents most directly counter the mechanism of opioid-induced constipation. Bulk-forming laxatives such as psyllium and methylcellulose should be avoided because they increase stool volume without promoting peristaltic action. For refractory opioid-induced constipation, a trial of oral naloxone, methylnaltrexone, or alvimopan may be initiated.[10] These μ-opioid receptor antagonists act locally to reverse the effects of opioids on the gut. There is minimal systemic absorption with oral naloxone and subsequently a low risk of precipitating opioid withdrawal or worsening pain at low to moderate doses (1.6-12 mg/day). Methylnaltrexone (administered subcutaneously)[10] and alvimopan (oral) do not cross the blood–brain barrier and therefore do not cause opioid withdrawal or worsening pain.

Nausea

Prochlorperazine (10 mg taken two or three times daily) or metoclopramide (10 mg taken three to four times daily) can prevent the nausea that occurs in most patients during the first days of opioid therapy. Relieving constipation or changing the opioid (e.g., from morphine to oxycodone) often eliminates the later development of nausea. Rarely, patients need oral or intravenous ondansetron (8 mg taken two or three times daily).

Respiratory Depression

Naloxone (Narcan), given intravenously, reverses opioid-induced respiratory depression, although repeated doses are often required.[10] Respiratory depression can occur in patients with mild to moderate pain during the initial use of opioids, although it is rare in patients with severe pain and in those chronically receiving opioids. Caution should be exercised before administering naloxone to patients who are chronically receiving opioids to avoid precipitation of severe pain and withdrawal. In such cases, it is inadvisable to administer the usual 0.4 mg/mL dose. Rather, 0.4 mg of naloxone should be diluted with 9 mL of saline and 1 to 2 mL (0.04-0.08 mg) of this dilute mixture given every 2 to 3 minutes until the patient is rousable and breathing at least 10 times/min. Do not give enough to fully waken the patient or withdrawal is likely to ensue.[1] In a comatose patient, endotracheal tube placement is recommended to prevent aspiration from the salivation and bronchial spasm that will be induced.[1] Naloxone should not be administered to an alert patient.

SPECIFIC CLINICAL PROBLEMS

Oral Complications

Oral complications of chemotherapeutic and bone marrow transplant regimens can be frequent causes of pain. A thorough dental evaluation and prompt treatment of infections can minimize the discomfort arising from underlying periodontal disease and caries; secondary bacterial, viral, and fungal infections; and mucositis. Preventive regimens include saline, sodium bicarbonate, chlorhexidine gluconate rinses, acyclovir, antifungals, and ice. Palifermin (keratinocyte growth factor [KGF-1]) is used for the prevention and treatment of mucositis induced by conditioning regimens for hematopoietic stem cell transplants.[10] Amifostine is a thiol compound that is a selective cytoprotective agent approved for salivary gland protection in patients receiving radiation therapy. The use of colony-stimulating factors in the treatment of oral mucositis remains investigational.

Viscous lidocaine (Xylocaine) or a slurry of sucralfate, dyclonine, or Kaopectate in diphenhydramine provides symptomatic treatment of mucositis pain. For individual lesions, benzocaine in Orabase can be helpful. Milk of magnesia, which dries out the mucosa, is not recommended. Recently, GelClair, a bioadherent gel that adheres to the oral surface, creating a protective barrier for irritated tissue, has had mixed results in small clinical trials. The more severe cases, occurring in bone marrow transplant recipients, usually require infusional opioid therapy delivered by standard drip or PCA. Pilocarpine (5-7.5 mg three or four times daily 1 hour before meals) may improve xerostomia from neck irradiation. However, caution is warranted because of reported side effects of glaucoma and cardiac problems. Sugar-free hard candy is also useful for opioid-induced xerostomia and dysgeusia.

Coagulation Disorders

Patients with inherited or acquired disorders of coagulation may have excessive risks of bleeding if aspirin or unselective COX-inhibiting NSAID-containing pain relievers are used.[10] If acetaminophen and celecoxib, which has no measurable effect on platelet function or bleeding, are not effective, these patients may obtain significant relief from the nonacetylated salicylates, salsalate (Disalcid), or choline magnesium trisalicylate (Trilisate), which do not prolong the bleeding time.[10] Because these agents share aspirin's ability to compete with warfarin for albumin binding,[10] the careful monitoring of patients' coagulation parameters is recommended when these drugs are started or stopped.

Postherpetic Neuralgia

Postherpetic neuralgia, defined as pain persisting beyond 4 months from the initial onset of the rash, can be a difficult problem for patients with hematologic disorders and has been the subject of several reviews. The anticonvulsant medications gabapentin and pregabalin are especially useful in reducing the lancinating component of the various pain syndromes generated by this infection.[10] The efficacy of gabapentin was demonstrated in a randomized, double-blind, placebo-controlled study to cause a statistically significant reduction in the average daily pain score compared with placebo. If the patient cannot tolerate gabapentin or pregabalin, amitriptyline is effective in 60% to 70% of patients. Elderly patients, however, often do not tolerate the anticholinergic side effects well. Nortriptyline (Pamelor), a less anticholinergic TCA, may be useful in these patients. Opioid analgesics provide modest pain control. The lidocaine patch (5%) is indicated for the relief of pain associated with post herpetic neuralgia, however, the role of lidocaine gel, or ointment (5% to 10%) has not been established. Topical capsaicin (0.075%), which depletes substance P, has shown efficacy in a

multicenter, double-blinded, randomized, placebo-controlled trial.[10] Capsaicin (0.075%) is also used for musculoskeletal discomfort. TENS devices provided relief for 1 year in 50% of postherpetic neuralgia patients, and 30% were pain free at 2 years. Patients with severe pain refractory to these therapies may benefit from a combination of intrathecal methylprednisolone and lidocaine. Acute herpes zoster pain may be diminished by a combination of acyclovir and prednisone.[10]

Sickle Cell Anemia

Patients with sickle cell anemia have chronic and episodic pain despite optimal medical therapy, and 60% of patients with sickle cell anemia will have an episode of severe pain each year. Chronic arthritic pain can be treated with physical therapy and full doses of antiarthritic medication, but some patients require low doses of chronic opioid therapy to maintain independent functioning. Several studies have confirmed the safety and efficacy of long-term opioids in the treatment of pain of nonmalignant origin. In some cases, joint replacement may be required.

When a patient with sickle cell anemia experiences pain, it is important to attempt to define the precise cause of the pain before attributing it to a vaso-occlusive crisis. Acute vaso-occlusive pain may occur along with the chronic pain caused by the long-term complications of compression fractures, avascular necrosis, arthropathies, fractures, avascular necroses, and leg ulcers.[28]

Treating patients with sickle cell pain is complex and requires understanding that much of the pain in adults with this illness is chronic with intermittent, recurring painful episodes. For mild pain, nonopioid therapy such as NSAIDS or acetaminophen with oxycodone or hydrocodone should be considered. However, because of possible compromise of renal blood flow in these patients and the risk of acute renal failure, NSAIDs should probably not be used beyond 5 days.[9] Uncontrolled severe pain accounts for more than 90% of hospital admissions in adults with sickle cell disease. Using short-acting analgesics on an "as-needed basis" exposes the patient to periods of insufficient analgesia, anticipation, and anxiety. Their repeated requests for medication to relieve their ongoing pain may be mistakenly interpreted as "drug-seeking behavior," and they may be unfairly stigmatized. Thus, intravenous analgesics should be started as a continuous infusion or with PCA. When adequate analgesia is obtained, a long-acting opioid, or a sustained-release opioid may be initiated with intermittent use of rescue medication. In adult patients with frequent episodes of painful crisis, the use of long-acting opioid medications reduced visits to the emergency department and hospitalizations and shortened the lengths of stay in hospital. Meperidine should be avoided in this population and has been associated with seizures in 1% to 12% of these patients.

Graft-Versus-Host Disease

For patients who have undergone bone marrow transplantation, GVHD can be a significant problem. The usual triad of GVHD includes hepatitis, dermatitis, and gastroenteritis. Patients are usually unable to take oral, rectal, subcutaneous, or transdermal opioids because of the effects on the skin (GVHD), lining of the gastrointestinal tract (mucositis, infection, and GVHD), and thrombocytopenia. Therefore, pain management with intravenous opioids is a necessity. The intestinal involvement that usually causes the most physical pain includes abdominal cramping and voluminous diarrhea. Treatment often begins with intravenous opioids given through a PCA pump. Addition of octreotide continuous infusion at 50 to100 μg/hr intravenously or intermittent dosing at 500 μg subcutaneously every 8 hours may be effective in decreasing the volume of diarrhea and level of abdominal pain.[10]

Peripheral Neuropathy Caused by Chemotherapy Agents

Several chemotherapy agents used in the treatment of hematologic malignancies can cause painful sensory peripheral neuropathy. The vinca alkaloids, most notably vincristine, are neurotoxic, but they are not always associated with painful neuropathy. Thalidomide, lenalidomide, bortezomib, cisplatin, oxaliplatin, and paclitaxel are all commonly used agents that carry a significant risk of causing painful peripheral neuropathy. The most common mechanism of neuropathy is damage to the axons starting with the most distal branches and is a result of chemotherapy's ability to damage DNA replication, leading to apoptosis. The major manifestations are burning paresthesias of the hands and feet and loss of reflexes. Paclitaxel also causes a motor neuropathy, which predominately affects proximal muscles.

Studies have evaluated numerous agents for prevention of painful peripheral neuropathy, although there have not been any magic bullets. Most of the research has focused on taxane and platinum-based chemotherapy agents. Amifostine and leukemia-inhibitory factor do not prevent neurotoxicity induced by these agents. Magnesium and calcium infusions have been shown to prevent neurotoxic symptoms associated with oxaliplatin without affecting its antitumor activity. Glutathione at doses of 1500 mg/m^2 administered before each dose of oxaliplatin for 12 cycles prevented grade 2 to 4 toxicities compared with placebo with no effect on response rate. Vitamin E has been shown to prevent neurotoxicity associated with cisplatin in small open-label evaluations. Glutamine 10 g three times daily for 4 days has had positive results as a neuroprotective agent in paclitaxel-treated patients. Acetyl-L-carnitine 1 g three times daily has been reviewed in the treatment of cisplatin- and paclitaxel-induced peripheral neuropathy, although no randomized studies have been done.

Treatment of chemotherapy-induced painful peripheral neuropathy includes the usual agents used for patients with neuropathic pain from any etiology (i.e., anticonvulsants, TCAs, and occasionally tramadol or opioids). In addition to treating these painful symptoms of neuropathy, the doses of the chemotherapy often require reduction or even discontinuation of therapy.

Problems of Elderly Patients

Pain management in elderly patients is a highly prevalent problem. It is complicated by difficulties in pain assessment and by the altered pharmacokinetics of opioids and of psychotropic adjuvant medications. Elderly patients may underreport pain.[10] Physicians may ascribe observed limitations in social contacts and physical activities to age-related changes when they are pain-induced limitations.

Elderly patients are particularly susceptible to the side effects of NSAIDs and opioids, and patients taking them should be monitored closely.[10] In elderly patients (70-89 years old), the volume of distribution for opioids is generally smaller, the drugs have longer plasma half-lives, and renal and hepatic clearances are decreased, all of which can prolong the duration of effect. The effective doses for these patients are half to one-fourth of those needed in younger patients. Drugs with short half-lives (e.g., morphine, oxycodone, hydromorphone) should be used, and initial doses should be low. Patients should be monitored carefully for the development of sedation or confusion, especially if they are receiving antihistaminic agents (e.g., famotidine, diphenhydramine), drugs with anticholinergic activity, or hypnotics.

Neuropathic pain syndromes are common in older adults, and the adjuvant analgesics gabapentin and pregabalin are often used. Common side effects include somnolence and ataxia that can be problematic in the geriatric population. Treatment should be initiated at 100 mg of gabapentin or 50 mg of pregabalin at bedtime, and close monitoring for side effects should occur before dose escalation. Acute urinary retention caused by opioids (especially in patients with prostatic hypertrophy) and the hypotension and tachycardia caused by tricyclic compounds can occur more frequently and be more

clinically severe in this population. The starting dose of nortriptyline should be low (usually 10 mg at bedtime), and the dose should be slowly increased as tolerated. Treatment of opioid-related urinary retention may include generic Proscar (5 mg/day) in patients with benign prostatic hypertrophy and bethanechol (10 to 50 mg three times daily) to help increase bladder smooth muscle tone.

ANTIEMETIC THERAPY

A number of effective antiemetic therapies are used to prevent the nausea and vomiting induced in patients by treatment of their hematologic disorders with chemotherapy or radiation therapy. These antiemetic therapies markedly improve patients' quality of life. The vast majority of patients can expect complete control of vomiting[29] (see box on Combination Antiemetic Regimens), and most patients also are free of nausea.

PATHOPHYSIOLOGY OF NAUSEA AND VOMITING

Nausea is the subjective sensation that precedes vomiting. It is caused by stimulation of one or more of four sites—the gastrointestinal tract, the vestibular system, the chemoreceptor trigger zone in the area postrema of the floor of the fourth ventricle, or higher centers in the CNS (Fig. 92-2). The gastrointestinal tract can activate the vomiting center by stimulation of mechanoreceptors or chemoreceptors on glossopharyngeal or vagal afferents (cranial nerves IX and X) or by release of serotonin from gut enterochromaffin cells, which in turn stimulates serotonin (5-HT3) receptors on vagal afferents. The vestibular system activates the vomiting center when stimulated by motion or disease (e.g., labyrinthitis) or when sensitized by medication (e.g., opioids). Histamine (H1) and acetylcholine M1 receptors are present on vestibular afferents. Endogenous or exogenous bloodborne toxins may activate chemoreceptors in the area postrema of the floor of the fourth ventricle via dopamine type 2 receptors. Finally, higher CNS centers may activate or inhibit the vomiting center. In addition, there may be direct activation of H1 receptors in the meninges secondary to increased intracranial pressure.

The means by which chemotherapy agents induce vomiting are still incompletely understood, but the most likely mechanism is believed to include stimulation of the chemoreceptor trigger zone.[10] Other causes of nausea and vomiting in hematologic patients include stimulation of the cerebral cortex, gastritis and gastroesophageal reflux disease, delayed gastric emptying, radiation enteritis, constipation, esophageal candidiasis, inner ear processes, hypoadrenalism, hypercalcemia, changes in taste and smell, and anticipatory nausea.[10]

Although the sites of emetic action of the chemotherapeutic agents have not been identified, blocking agents directed against type 3 serotonin receptors (5-HT3 receptors), dopamine (D2) receptors, and neurokinin (NK1) receptors have been effective in inhibiting chemotherapy-induced nausea and vomiting (CINV).[10] Higher centers in the brain, such as the cortex, are also believed to be involved in producing anticipatory nausea and vomiting (ANV). Cognitive therapy, as well as antianxiety and amnesic agents, may provide effective antiemesis.

EVALUATION

Risk factors for developing CINV include age younger than 60 years, female gender, history of motion sickness, and hyperemesis gravidarum.[10] Patients who have a history of alcohol intake of more than five alcoholic drinks per day (>100 g of alcohol) tend to have less nausea and vomiting. This has been studied carefully in patients receiving high-dose cisplatin therapy but has been anecdotally observed in patients receiving other agents.

Anticipatory Nausea and Vomiting

Anticipatory nausea and vomiting is believed to be a classic conditioned response.[10] Chemotherapy administration (the unconditioned stimulus) results in nausea and vomiting (the unconditioned response). Clinic sights, smells, and sounds are the conditioned stimuli. After frequent pairings of chemotherapy administration and the clinic's sights, smells, and sounds, the responses (nausea and vomiting) can be triggered in the absence of any chemotherapy by the clinic's sights, smells, or sounds or simply by seeing clinic personnel even at a location distant from the site of treatment.

Patients who are at risk for developing ANV are those who have already experienced posttreatment nausea and vomiting. The risk of developing ANV increases with the increasing frequency, severity, and duration of the symptoms. Other possible predisposing factors include susceptibility to motion sickness, awareness of tastes or odors during infusions, younger age, lengthier infusions, greater autonomic sensitivity, and general anxiety or emotional distress.[10]

Acute and Delayed Chemotherapy-Induced Nausea and Vomiting

Acute CINV is defined as nausea, vomiting, or both occurring within 24 hours of administration of the agent. The emetogenic potential of the drugs[29,30] is shown in the box on the Emetic Risks of Chemotherapy. Although most drugs produce emesis 1 to 2 hours after they are given (in patients who have never before received chemotherapy), the onset of emesis from high-dose intravenous cyclophosphamide is delayed until 9 to 18 hours after treatment, and nausea and vomiting from high total doses of cisplatin can occur 24 to 72 hours later.

THERAPY

Anticipatory Nausea and Vomiting

The best way to prevent ANV is to give aggressive antiemetic therapy and to treat anxiety with the appropriate agents (see Benzodiazepines). However, in patients for whom this approach has not been successful and in whom ANV develops, a variety of behavioral techniques have been helpful.[10] These include hypnosis, progressive muscle relaxation with guided imagery, systemic desensitization, and distraction. Results may be optimized if a therapist trained in these techniques works with the patient, but patients can use progressive muscle relaxation with guided imagery on their own.

Acute and Delayed Chemotherapy-Induced Nausea and Vomiting

Most studies of the potent antiemetic agents have been conducted in patients receiving therapy with cisplatin, a drug of high emetic potential. Although cisplatin is not generally used to treat patients with hematologic malignancies, the data are included in the following discussion because the findings can be extrapolated to other drugs of equivalent or less emetogenic potential. When available, data regarding efficacy in patients receiving radiation therapy or emetogenic drugs commonly used to treat hematologic disorders are reviewed. The choice of antiemetic agents depends on the emetogenic potential of the chemotherapy or radiation therapy regimen, the side effect profiles of the antiemetic agents and patient preferences and characteristics.

The emetogenic potentials of commonly used chemotherapeutic agents are outlined in the box on the Emetic Risks of Chemotherapy. Younger patients have a higher incidence of CINV and of metoclopramide-related acute dystonic reactions; trismus or torticollis was seen in only 2% of patients older than 30 years of age but in 27% of younger patients. Even if they are receiving only moderately emetogenic therapy, they should be given an antiemetic regimen for high-emetogenic drugs.[29] Younger patients find cannabinoids (e.g., Marinol) more effective than do older patients because they can better tolerate the side effects associated with the therapeutic doses of these agents. Elderly patients also have high risks of extrapyramidal side effects and are more susceptible to anticholinergic and sedating side effects. 5-HT3 receptor antagonists are therefore preferred to regimens containing metoclopramide and diphenhydramine. Patient

Emetic Risks of Chemotherapy

High (>90%)

Carmustine (>250 mg/m²)
Cisplatin (≥ 50 mg/m²)

Combination Antiemetic Regimens

Highly Emetogenic
Prophylactic

5-HT3 RA PO or IV 30 minutes before chemotherapy each day for the duration of chemotherapy plus
Dexamethasone, 12 to 20 mg PO or IV 30 minutes before chemotherapy each day for the duration of chemotherapy plus
Aprepitant, 125 mg PO 1 hour before chemotherapy (use 12-mg dose of dexamethasone)

To prevent or manage delayed nausea and vomiting after chemotherapy

For 2 to 5 days after chemotherapy:
Dexamethasone, 8 mg PO each day
Aprepitant, 80 mg PO each morning on days 2 and 3 (see above)

Moderately Emetogenic
Prophylactic

5-HT3 RA PO or IV 30 minutes before chemotherapy ±
Dexamethasone 8-12 mg PO or IV 30 minutes before chemotherapy

To prevent or manage delayed nausea and vomiting

Dexamethasone 8 mg PO once daily for days 2 and 3

Low Emetogenic Potential

Dexamethasone 8 mg PO or IV 30 minutes before chemotherapy as needed *or*
Metoclopramide 10-20 mg PO or IV 30 minutes before chemotherapy as needed *or*
Compazine 10 mg PO or IV 30 minutes before chemotherapy as needed

preferences regarding degree of alertness can help the health care provider choose an antiemetic regimen, as can the level of anxiety the provider observes in the patient.

Serotonin Receptor Antagonists: Ondansetron, Granisetron, and Palonosetron

Ondansetron, granisetron, and palonosetron are the best studied of the 5-HT3 receptor antagonists (5-HT RAs). This class also includes the drugs dolasetron and tropisetron. Several studies of patients receiving regimens that included cyclophosphamide, methotrexate, or doxorubicin showed significant efficacy and the superiority of ondansetron over placebo.

Ondansetron also demonstrates efficacy in patients with emesis (induced by non–cisplatin-containing chemotherapy) that has been refractory to standard antiemetics, with complete control achieved in 50% of these patients. When dexamethasone is added, the rate of control is as high as 91%.

Ondansetron effectively prevents nausea and vomiting in patients treated with highly emetogenic agents for acute leukemia or multiple myeloma (i.e., high-dose melphalan) or who are being prepared for bone marrow transplantation with cyclophosphamide and total-body irradiation.[29,30] In the transplantation recipients, 83% of patient-days were without any vomiting or retching, and in another 10%, there were no more than two emetic episodes. Ondansetron is also effective in preventing emesis induced by single- or multiple-fraction radiation therapy.[10] Ondansetron is as effective as high-dose metoclopramide in preventing nausea induced by cisplatin, cyclophosphamide alone, or doxorubicin chemotherapy.

Oral granisetron has shown equivalence to ondansetron in studies of patients receiving cisplatin- or carboplatin-based regimens. In patients receiving moderately emetogenic therapy, oral granisetron with dexamethasone was as effective as intravenous ondansetron and dexamethasone. Oral or intravenous granisetron and dexamethasone were effective in a bone marrow transplantation program in which patients were treated with Cytoxan and total-body irradiation, and these agents, along with oral prochlorperazine, were also effective in patients undergoing peripheral blood stem cell transplantation for which patients received Cytoxan, VP-16 or thiotepa, and cisplatin.

Palonosetron is a second-generation 5-HT3 RA with higher potency, stronger receptor binding activity, and longer half-life than the other drugs in this class.[10] Palonosetron 0.25 mg intravenously has been studied in moderately and highly emetogenic chemotherapy. Several subgroup analyses of the registrational noninferiority trials have been reported in which palonosetron was superior. Current studies seek to find palonesetron's place in therapy. Ondansetron and the other 5-HT3 RAs have far fewer side effects than high-dose metoclopramide. Reports of extrapyramidal reactions are rare,[10] and sedation, dystonic reactions, akathisia (e.g., severe restlessness, "ants-in-the-pants" feeling), and tardive dyskinesias do not occur. Patients can develop constipation, mild headache, and elevated levels of transaminases.

Corticosteroids

The mechanism of the antiemetic action of corticosteroids remains undefined. Corticosteroids are effective when used alone to prevent emesis induced by agents of moderate or low emetogenic potential.[29,30] They are also a useful component of antiemetic therapy regimens that include ondansetron, granisetron, aprepitant, or metoclopramide and add efficacy in randomized controlled trials.[29,30] Dexamethasone and methylprednisolone are the best-studied agents, but no trials have demonstrated the superiority of one corticosteroid over another.

Metoclopramide

Metoclopramide is a substituted benzamide that promotes gastric motility and reduces the emetic activity of chemotherapy agents by blocking dopamine receptors (at low to moderate doses) and 5-HT3 receptors (at high doses) in the chemoreceptor trigger zone. Because of a more favorable side effect profile, 5-HT3 antagonists have replaced high dose metoclopramide. At lower doses (5-10 mg orally or intravenously every 6 hours), metoclopramide is useful in treating mild to moderate and delayed nausea and vomiting. Delivery of the drug on a schedule that maintains adequate levels during expected emesis appears to be important.

The side effects, which may be caused by the interaction of metoclopramide with dopamine receptors, can be quite troublesome. They include akathisia, dystonic reactions (age related), sedation, and diarrhea. Benzodiazepines such as lorazepam and β-blockers such as propranolol can prevent or reverse the akathisia, and diphenhydramine or benztropine can prevent or reverse the dystonias. However, these agents induce additional side effects, including dry mouth and sedation. Short-term, high-dose metoclopramide or long-term use at usual doses has been associated with persistent and disabling movement disorders, especially tardive dyskinesias.

Neurokinin-1 Inhibitors

Substance P can cause emesis, and it appears to play a role in chemotherapy-related nausea and vomiting. Its effects are mediated through NK-1 receptors.[10] Agents that cross the blood–brain barrier and inhibit NK-1 activity (e.g., aprepitant) are more effective than a 5-HT3 RA and dexamethasone alone in moderating acute chemotherapy-related nausea and vomiting, and they are particularly effective in decreasing delayed nausea and vomiting occurring after cisplatin chemotherapy.[10,29] The need for continued dexamethasone with the NK-1 inhibitor has not yet been determined, and comparisons with the metoclopramide and dexamethasone regimen for delayed nausea and vomiting have not yet been performed. Aprepitant is an inhibitor of CYP3A4 and therefore may cause elevation of chemotherapy agents primarily metabolized by this route; however, these elevations are not considered clinically significant, and there are no recommend dose adjustments. Aprepitant can cause significant decreases in the prolongation of the international normalized ratio induced by warfarin. Fosaprepitant, the intravenous prodrug of aprepitant, has demonstrated equivalent efficacy to the 3-day oral regimen as a single dose at 150 mg on day 1.

Combination Antiemetic Therapy

For drugs with low or minimal emetogenic potential, no antiemetic drug may be needed, or a single agent such as dexamethasone or metoclopramide may be sufficient. For drugs with higher emetogenic potential, standard antiemetic treatment usually includes combinations of several antiemetic agents along with agents designed to treat anxiety, cause amnesia, or prevent known side effects. These combinations include a 5-HT3 receptor antagonist such as ondansetron and a corticosteroid such as dexamethasone for moderately emetogenic regimens.[29] For highly emetogenic combination chemotherapy or regimens that include two moderately emetogenic agents, such as cyclophosphamide and Adriamycin, aprepitant (NK-1 inhibitor) should be added to the antiemetic combination.[29] Optional lorazepam may be added for anxiety-related symptoms. It is important to give antiemetic therapy before administering chemotherapy agents and to continue for about 24 to 72 hours after the drugs have been given to prevent emesis.

Benzodiazepines

The benzodiazepine lorazepam has only mild antiemetic activity when used as a single agent. It is used frequently in the treatment and prevention of nausea and vomiting, particularly when anxiety is associated with the nausea and vomiting. It markedly decreases anxiety and the akathisia associated with metoclopramide therapy and induces a dose-related memory loss and marked sedation.

Other Drugs

Other agents that are more active than placebo include the butyrophenones haloperidol and droperidol, the phenothiazine prochlorperazine, and the cannabinoids dronabinol (THC) and nabilone. These agents are less effective drugs than the agents previously mentioned, and all cause sedation. The butyrophenones produce dystonic reactions, akathisia, and occasionally hypotension. The cannabinoids cause ataxia, dry mouth, orthostatic hypotension and dizziness, euphoria or dysphoria, and a feeling of being "high." Scopolamine, a centrally-acting anticholinergic, can be effective for patients with a vertiginous component to their nausea (see box on Combination Antiemetic Therapy). Olanzapine has been shown to improve control of both acute and delayed nausea and vomiting in highly and moderately emetogenic chemotherapy when used in combination with dexamethasone and a 5-HT3 receptor antagonist.

CHAPTER 93

PALLIATIVE CARE

Kristen G. Schaefer, Janet L. Abrahm, and Joanne Wolfe

Palliative care is specialized care for children and adults with a focus on individual patient and family goals, values, preferences, and expressed needs in the face of serious illness. Palliative care practitioners need to have expertise in communication, in treatment of physical symptoms, and in relieving sources of social, psychologic, and spiritual distress. Each section of this chapter will first review core elements of palliative care for children and then for adults.

PEDIATRIC PALLIATIVE CARE

I just wish that I had armfuls of time.

— (4-year-old child)[1]

Pediatric palliative care is an emerging frontier in the comprehensive care of children. The 2003 Institute of Medicine report *When Children Die: Improving Palliative and End-of-Life Care for Children and Their Families*[2] (Table 93-1) highlights its critical importance. In the last few years, a powerful statement by the American Academy of Pediatrics, the findings of a comprehensive British report on children with life-threatening and terminal conditions, and two earlier Institute of Medicine studies set the stage for this seminal report. A comprehensive definition is as follows:

Palliative care for children and young people with life-threatening illness is an active and total approach to care, embracing physical, emotional, social, and spiritual elements. Pediatric palliative care focuses on optimizing quality of life and well-being for patients and families by using expert symptom management, caregiver support and respite, and specialized care at the end of life and in bereavement.

As this field develops, there is much debate about the terms *life-limiting* and *life-threatening.* Life-threatening is a broader concept, in that it includes illnesses for which cure is possible, although the threat of a fatal outcome exists (e.g., childhood malignancies). Of course, an illness may begin as life-threatening and convert into a life-limiting condition, as when a child relapses and curative options no longer exist. Life-limiting conditions are those for which there is no reasonable chance of cure from the outset; even if children survive for years and decades, they will not live out a normal life expectancy.

In addition to end-of-life care for the child (and bereavement follow-up for the family), pediatric palliative care includes care throughout the trajectory of the child's illness, including respite as an important component. Specific issues related to palliative care for pediatric patients and their families include the following[3]:

- Smaller numbers of dying children than adults mean that there is less professional expertise and underrepresentation of children in palliative care protocols.
- The heterogeneity of illnesses, many rare, requires the involvement of many disciplines and specialists.
- Many children have genetic diseases, so there may be more than one affected child in a family.
- The time course of some illnesses is extremely variable. Pediatric palliative care may extend over years, even decades.
- A broad developmental spectrum is represented, including changes in the individual child through time.
- The underlying principles and ethics of palliative care are universal across the life span. However, as in all specialties, children bring with them unique issues and dilemmas.
- A child or adolescent diagnosed with a life-threatening or life-limiting illness throws an assumed sequence out of order. A time of role reversal is expected, when children will care for dying parents. When parents instead find themselves watching their child face death, a sense of tragic absurdity prevails. Not only is time shortened, but its order is shattered. A child or adolescent with a life-threatening illness represents a premature separation to the family. Even before the child has become a differentiated individual through a natural developmental sequence, that child is wrenched away. There is little preparation for separation by death when a psychologic separation has not yet been effected. The adolescent who is beginning to negotiate an independent existence is often the hardest to face when that "moving forward" is irreversibly halted, or at least disrupted. A child has not even had the time to begin to form life goals.[4]
- The necessity for palliative care—the concept and the clinical approach—may emerge at different points in the illness trajectory, depending on the prognosis for the child, the decisions that must be made in choosing treatment options, and always, the management of pain and suffering in the provision of optimal quality of life. One of the foremost goals is to initiate palliative care for children earlier in the illness trajectory—in a proactive manner—so that effective care planning can be implemented. Care of the family, with a particular focus on the young siblings, is a priority.

ADULT PALLIATIVE CARE

Palliative care for adult patients involves the same specialized, interdisciplinary, patient- and family-centered attention to physical comfort, psychologic needs, social and spiritual sources of distress, and the alignment of treatment plans with patients' and families' goals of care. Although often conflated with end-of-life care or hospice care, the specialty aims to improve quality of life for patients throughout the course of serious illness, from diagnosis through the final stages, including simultaneously with life-prolonging or curative therapies.[5] In 2006, hospice and palliative medicine was accepted as a specialty by the American Board of Medical Specialties. In 2007, the Accreditation Council for Graduate Medical Education began accrediting fellowship programs, and the first qualifying examination in hospice and palliative medicine was given in 2008. Emerging evidence suggests that concurrent palliative care in advanced illness can decrease costs and improve outcomes,[6] and patient access to high-quality specialty-level palliative care is becoming standard of care at most academic cancer centers.

Table 93-1 Summary of the Institute of Medicine Report: *When Children Die: Improving Palliative and End-of-Life Care for Children and Their Families*

IMPROVE ORGANIZATION AND DELIVERY OF CARE
Emphasis is placed on the development of care guidelines and protocols in all pediatric settings, the development of regional information programs and resources in rural areas, and policies and procedures for involving children in decision making.
REFORM FINANCING OF PALLIATIVE SERVICES AND HOSPICE CARE
Vast changes in public and private health coverage: add hospice, change eligibility rules, provide outlier payments, extend coverage for counseling family members and for bereavement follow-up.
BETTER PREPARE HEALTH PROFESSIONALS
Create educational experiences and curricula that will provide basic and advanced competence in palliative, end-of-life, and bereavement care.
STRENGTHEN RESEARCH BASE FOR EFFECTIVE CARE
Emphases include appropriate quality-of-life measures, effective symptom management, impact of perinatal death on parents and siblings, impact of sudden death on family and professional caregivers, efficacy of bereavement interventions, models for provision of care, financing alternatives, effective strategies for educating professionals.

From Institute of Medicine: *When children die: Improving palliative and end-of-life care for children and their families,* Washington, DC, 2003, National Academy Press.

Table 93-2 Breaking Bad News

1. Make yourself, the patient, and the family comfortable.
2. Find out what they know.
3. Indicate that you are planning to tell them something that is unpleasant and may be disturbing.
4. Find out whether they want to be told, or whether they want someone else to be told.
5. Find out how much they want to know (i.e., the big picture versus all the details).
6. Tell them in words they can understand, allowing time for questions along the way.
7. Respond to their feelings.
8. Let them know that this is only the first of many discussions with you.
9. Ask them to summarize what they heard you say; ask if they have further questions.
10. Arrange your next meeting with them.

From Abrahm JL: Update in palliative medicine and end-of-life care, *Annu Rev Med* 54:53, 2003.

COMMUNICATION

Good communication can dispel fears of abandonment. Breaking bad news and discussing prognosis with patients with advanced disease are occasions when physicians can demonstrate their commitment to an ongoing partnership with patients and families. Conversations must demonstrate respect for cultural differences[7] and the conviction that growth can occur even at the end of life.[8] If done well, the groundwork will be laid for further discussions of patient hopes and fears, goals, values, and spiritual concerns that form the basis of decisions about resuscitation and artificial life support.

Communication with a child …

> *When I first heard my diagnosis, one question kept going around and around in my head: "How long do I have, Doc?"*
>
> *— (12-year-old child)*[1]

Children with serious hematologic disorders have usually lived with the illness over a prolonged period of months or years. Their knowledge, understanding, and awareness of their precarious life situation is often profound, at physical, cognitive, and emotional levels.

> *The doctors think my bone marrow is fine for now—and for now is for now.*
>
> *— (8-year-old child)*[4]

The protective stance of the past stated that disclosure to the child of his or her prognosis (and even, in some instances, the diagnosis) would cause increased anxiety and fear. Since the 1980s, however, a shift toward open communication has been evident.[9] To shield the child from the truth may only heighten anxiety and cause the child to feel isolated, lonely, and unsure of whom to trust.

In communication with the life-threatened child at any juncture in the illness, the precedent for a climate that enables such honest interchange is created from the time of diagnosis. The individual child's competence and vulnerability serve as the context for decisions regarding disclosure at any point in the illness trajectory. Considerations about what or how much to tell include the child's age, cognitive and emotional maturity, family structure and functioning, cultural background, and history of loss.[1] These same factors apply at the end of life, with extreme sensitivity to how the parents have chosen to inform the child throughout the illness experience, how the child has understood and processed information up to this time, and what the child is now asking—implicitly and explicitly—about his or her situation.

For adult patients with advanced cancer, having had a discussion about end-of-life wishes with one's physician has been shown to correlate with less aggressive medical care near death, earlier hospice referrals, cost savings at the end of life, and improved bereavement adjustment for caregivers.[10] Furthermore, having had conversations about end-of-life wishes is not associated with higher rates of major depressive disorder or more worry. Proactive, direct communication with patients and their families about approaching and managing the end of life can be a satisfying and rewarding part of patient care. However, more training in palliative care clinical and communication skills is needed during hematology/oncology fellowship and in continuing medical education settings to ensure competency in these areas.

Breaking Bad News

Table 93-2 contains an outline of the suggested steps to take when breaking bad news.[11] For patients with advanced disease, the goal is to establish or strengthen trust and reassure them that the physician is committed to caring for them. To do this well, physicians need to believe that they have not failed the dying patient, medicine has.

Prognosis and Decision Making

Surveys of bereaved parents indicate that physician communication about prognosis is not optimal. At the same time, emerging data suggest that bereaved parents consider high-quality communication as the most important value when reflecting on physician quality of care.[12] Parents value clear information that is communicated sensitively and includes the child, when developmentally appropriate. When it comes to discussing prognosis, a majority of parents want as much information as possible.[13] Furthermore, although many parents find prognostic information about their child upsetting, they still want prognosis to be discussed. The data suggest, however, that parents are overly optimistic about the child's chances of cure in comparison to physicians, and this is especially true when the prognosis is uncertain. Being aware of these trends may help physicians to discuss prognosis with greater clarity.

One side of my head says: "Think optimistic." The other side says: "What if this treatment doesn't work?"

— (11-year-old-child)[1]

The child is often aware of the diminishing curative or life-prolonging options that he or she faces. It is at this time that the child may ask anxiously: "What if this medicine doesn't work? What will you give me next?" The child experiences a profound sense of loss of control. It is at this time that families are confronted with a series of decisions regarding the nature and intensity of medical interventions they wish to pursue. This process can be excruciating: they do not want their child to suffer more, yet they often cannot tolerate the thought of "leaving any stone unturned" in the quest for a cure or prolonged time, however minuscule the chance.[14] The physician and team's role shifts from leadership in recommending a curative treatment plan to the clarification of experimental and palliative options and consequences. In most instances, the parents make the decision; however, to varying degrees, the child may be involved in such discussions.[15] Hinds et al[15] have demonstrated that when asked in a sensitive manner, children as young as 10 years of age are able and willing to talk about their experiences and end-of-life decisions.

During the last decade there has been increased recognition of the child's participation in making treatment decisions. Crucial to this process is an assessment of the child's or adolescent's ability to appreciate the nature and consequences of a specific medical decision. This becomes particularly complex when the wishes of the child differ from those of the parents. Because actual assessment tools are only in the early stages of development, professionals must rely exclusively on their clinical judgment to assess children's understanding of the contingencies they are facing. This is often a juncture when input from members of the interdisciplinary team can be crucial: children often express their understanding, awareness, and thoughts about treatment options and living or dying to individuals other than their parents or primary physician.

The following example illustrates the remarkable capacity of a young child to address the transition to palliative care.

A 7-year-old girl told her parents that she was too tired to fight anymore, and that she wanted to give up. She added: "If I have to continue suffering, I would rather be in heaven." These statements were major determinants in the parents' choosing a palliative care plan without any further attempts at life-prolonging treatment. She went home on hospice care and died peacefully several weeks later.[1]

Adult patients and families want to be prepared for the end of life. The vast majority (80% to 98%) want to be able to name someone to make decisions, know what to expect about their physical condition, have financial affairs in order, know that the physician is comfortable talking about death and dying, feel that the family is prepared for their death, have funeral arrangements in place, and have treatment preferences in writing. For this to happen, patients must know how long they are likely to have left to live.[16] Although most patients report wanting prognostic information from their oncologist, patients with advanced refractory disease may not ask about their prognosis, and oncologists often do not initiate the discussion. In one recent observational study, only half of patients were told unambiguous prognostic estimates for mortality or cure during their first oncologic visit for a hematologic malignancy.[17]

There are significant benefits from having a discussion of prognosis with a relatively asymptomatic patient with a limited time left to live and his or her caregivers. Patient preferences for resuscitation are affected by the likely outcome of treatment and by their understanding of their prognosis. It is equally important that patients with very poor prognoses understand how limited they really are. Patients who thought they had a greater than 10% chance of surviving 6 months, for example, usually wanted to be resuscitated. Patients who thought they had a less than 10% chance of surviving 6 months overwhelmingly chose comfort care and did not want to be resuscitated.[18] Discussions of prognosis can be very painful for clinicians, because they may cause feelings of guilt, failure, or sadness. Clinicians interested in improving their skills may refer to practical educational handbooks[19] and articles that outline how to discuss these issues both with patients who want to know their prognosis and with those who do not or are ambivalent.

Cultural Considerations

Ethnicity, culture, socioeconomic status, religion, and religious background all affect the ways patients experience illness and face death.[20] Autonomy may be expressed in a number of ways. For example, non-Hispanic whites prefer to have immediate family only present, whereas African Americans want their extended family, friends, and pastor. African Americans are also more interested in spiritual concerns, lack of trust, concerns about do not resuscitate (DNR) orders and hospice, allowing adequate time for decisions, and not feeling pressure to make them.[7] The best way to show respect for patient and family views is to individualize the approach with attention to language, religious beliefs/concerns, cultural context, health beliefs, decision-making patterns, and social support/resources. Qualified interpreters should be provided whenever the clinician is not fluent in the patient's language.

Impact on Hope

The rigors of treatment regimens and the physical and emotional demands of the complex care required for advanced disease tend to isolate patients and their families and focus all their hopes on disease remission. They may have forgotten how to hope for anything else. Physicians and the teams they work with can help patients with advanced hematologic diseases develop new kinds of hope by encouraging them to reintegrate into activities that were meaningful before their disease began and they rearranged their lives around treatment schedules. Paradoxically, discussion about limited prognosis is likely to lessen fears of abandonment and strengthen the trust patients have in the oncology team. Most patients hope for time to say their goodbyes, to bring closure to their lives, and to leave their legacies: videos, scrapbooks, letters, and presents for children or grandchildren for events far into the future.

As disease progresses, despite ongoing treatment, patients who have begun to reengage in non–treatment-related activities and who have developed a broader relationship with their physicians are more likely to understand that the physician is not abandoning them when he or she says that the goals of treatment should be comfort. Such patients do not complain that stopping treatment is "waiting around to die" because they have other activities to fill their days.

CAREGIVERS

Families and other nonprofessional caregivers provide the vast majority of care for patients with advanced cancer, which is thought to be worth the equivalent of more than $250 billion dollars a year. Caregivers of patients with advanced illness are stressed by the patient's disability and degree of suffering, the lack of coordination of care, and underlying family, work, or financial pressures.[21,22] Caregiving can take a physical and psychologic toll on the caregivers, with increased prevalence of depression, decrease in self-care and preventive care, and perhaps increased mortality. Providing information and increasing coping skills can improve caregiver knowledge and skill, but even providing respite care has not lessened the sense of burden or depression. As many as 32% of caregivers either have a major psychiatric condition (panic disorder, major depression, posttraumatic stress disorder, or generalized anxiety disorder), or access mental health services after the patients' diagnosis. Caregivers are likely to need the support of many members of the team therefore to continue in their difficult role.

RELIEF OF SUFFERING

Suffering includes physical, psychologic, social, and spiritual dimensions.

Symptom Management in Children

Therapist: If you could choose one word to describe the time since your diagnosis, what would it be?

— Child: PAIN.[1]

Maintaining patient comfort is a critical issue throughout treatment, as well as during the end stages of life. Although effective pain control is a hallmark of palliative care, pain is only one of many distressing symptoms.[3] The spectrum of physical symptoms includes (although it is not limited to) dyspnea, fatigue, seizures, loss of appetite, nausea and vomiting, constipation, and diarrhea. Several comprehensive studies,[23] in which bereaved parents were interviewed regarding their children's end-of-life care, indicated that optimal symptom management is still far from being achieved, even in major pediatric teaching centers. More than 10% of parents considered hastening their child's death; this was more likely if the child was in pain.[24] Relief of a child's end-of-life distress may have long-lasting implications for bereaved parents, who are negatively affected by the child's experience of pain years beyond the death.

Psychologic symptoms such as depression and anxiety are also prevalent in children at the end of life.[23] Children also experience existential concerns. Creating opportunity for communication around these sources of distress involves using creative strategies that incorporate the developmental stage of the child. Strategies may involve verbal communication using open-ended questions such as "What are you hoping for?" and "What are you worried about?"

However, many children communicate best through nonverbal means such as artwork and music. Children may be more willing to "talk things over" with puppets or stuffed animals rather than real people. Importantly, euphemistic expressions about death can be confusing or even frightening (for instance, equating death with sleep may result in the child's being afraid of going to bed) and should be avoided.

Needless to say, parents of children with life-limiting conditions also experience distressing symptoms such as anxiety, depression, and spiritual concerns.[25] Recognition by the pediatric clinician may serve families well while the child is alive and during bereavement.

Symptom Management in Adults

Pain and antiemetic therapy for adults is reviewed elsewhere in this volume. Anxiety, depression, delirium, and control of symptoms occurring in the last days of life are reviewed subsequently. Interested readers are referred to other references for reviews of assessment and management of other common troubling symptoms and syndromes in adults (e.g., posttraumatic stress disorder, substance abuse, major psychiatric illnesses, personality disorders, or demoralization).[26,27]

Among social sources of distress are financial concerns and with increasing debility, loss of independence and sense of contribution and efficacy. Worries about burdening the family or that the family will fail them when they really need them may lead patients to request physician-assisted suicide. Social workers are the key team members who can help alleviate or at least ameliorate these sources of distress and can help the caregivers cope.

Physicians should also explore religious and spiritual concerns and understand what rituals will be important at the end of life.[28] Spiritual and existential distress occur when individuals are unable to find sources of meaning, hope, love, peace, comfort, strength, and connection in life or when there is dissonance between their beliefs and what is happening to them. Patients who use "positive" religious coping (e.g., prayer, feeling a sense of connectedness to a religious community, having a positive relationship with God) have been found to have better mental health status, growth with stress and in the spiritual dimension, as well as a better overall quality of life. Patients who use "negative" religious coping (e.g., ascribe their illness to a punishing God or one who has abandoned them) have a poorer quality of life.[28] Clinicians should therefore include either a formal or informal spiritual assessment for all patients diagnosed with life-limiting diseases. Psychologic, spiritual, or religious counseling may be needed to help these patients reconnect and find what they have lost.

PSYCHOLOGIC CONCERNS

As Block[27] states in her 2006 review of psychologic issues in end-of-life care, "grief, sadness, despair, fear, anxiety, loss and loneliness are present, at times, for nearly all patients facing the end of their lives." For patients to cope with the diagnosis and its implications, they need "good communication and trust among patient, family, and clinical team, the ability to share fears and concerns, as well as meticulous attention to physical comfort and psychological and spiritual concerns."[28] For a thorough discussion of the patient assessment (which includes "developmental issues; meaning and impact of illness; coping style; impact on sense of self; relationships; stressors; spiritual resources; economic circumstances; physician-patient relationship"), please refer to Dr. Block's review.

Anxiety and Depression

It is noteworthy that the psychologic states of depression and anxiety are often not recognized as symptoms in children, and in many instances are inadequately addressed. Significant anxiety is found in approximately 25% of adult patients with cancer, and anxiety symptoms can interfere with ability to receive care.[29] Patients with panic disorders, agitated depression, phobias, obsessive-compulsive disorder, delirium, posttraumatic stress disorder, or adjustment disorders can all present with anxiety.[28] Anxiety in dying patients may arise from worries about the future (uncontrolled symptoms, family concerns, or concerns about death), isolation from loved ones, sepsis, hypoxia, metabolic abnormalities, withdrawal from alcohol, opioids or benzodiazepines, drug reactions (e.g., akathisia from metoclopramide, phenothiazines, and butyrophenones; paradoxical agitation from benzodiazepines and olanzapine), and uncontrolled pain. Nonpharmacologic treatments, such as relaxation training, hypnosis, supportive psychotherapy, and counseling, are very effective. Pharmacologic treatments usually include benzodiazepines (e.g., the short-acting lorazepam, starting dose 0.5 to 2 mg every 8 hours as needed; or long-acting clonazepam, starting dose 0.25 to 0.5 mg PO [orally] two times daily), selective serotonin reuptake inhibitors (SSRIs; see later), and, when there is evidence of delirium, neuroleptics (see later).

At least 7% of patients with advanced cancer meet criteria for a major depressive disorder, 41% of whom had a previous history of major depressive disorder.[30] It can be difficult to discern which patients with advanced disease are depressed or grieving. The usual somatic signs of depression or grief (e.g., anorexia, sleep disturbances, fatigue, or weight loss) are common in this population. Depressed patients, however, will be anhedonic and feel worthless, guilty, hopeless, or helpless. Grieving patients, in contrast, are very sad, but they are able to find happiness in some circumstances and can plan for the future.[28] Pain, a past or family history of substance abuse, depression, or bipolar illness are major risk factors for depression. Terminally ill patients responding "Yes" to the screening question "Are you depressed?" are very likely to be confirmed as depressed in a more comprehensive evaluation. Useful follow-up questions include "How do you see your future?" "What do you imagine is ahead for yourself with this illness?" "What aspects of your life do you feel most proud of? Most troubled by?"

As part of the treatment of depression, pain must be brought under control. Counseling can explore patient fears, provide emotional support, and help patients review their lives and find the

Table 93-3 Delirium

Drug	Dose	Comment
ANTIPSYCHOTICS		
Haloperidol	0.5-5 mg PO, IM, subcutaneously, IV	Do not exceed 20 mg in 24 hr Repeat q 2-12 hr prn Maintain the patient on the effective dose (divided into a bid dose), then taper over 2 wk, as tolerated Oral dose is 60%-70% as potent as parenteral dose
Quetiapine	25-200 mg PO qhs	Particularly useful in elderly patients with evening delirium Start 25 mg hs for 3-4 days
Olanzapine	2.5-15 mg PO bid	Start 2.5-5 mg PO bid (2.5 mg for elderly patients); can use q 4-6 hr prn agitation Maintain the patient on the effective dose (divided into a bid dose), then taper over 2 wk, as tolerated; also antiemetic
Chlorpromazine	12.5-50 mg PO/IV/PR	Sedating; in very agitated patients, may repeat q 1-4 hr until sedated
SEDATIVES		
Lorazepam	0.5-2 mg q 1-4 hr	Add to haloperidol/olanzapine for patients with an agitated delirium Tablets can be used PR for terminal delirium
Diazepam	10-30 mg daily	Useful PR for patients unable to take oral medication
Clonazepam	0.5-2 mg bid to tid	Tablets have been used PR for terminal delirium; do not exceed 20 mg/24 hr
Midazolam	30 to 100 mg over 24 hr	IV drip or subcutaneous infusion for terminal delirium

Modified from Abrahm JL: *A physician's guide to pain and symptom management in cancer patients,* ed 2, Baltimore, 2005, Johns Hopkins University Press; and Miovic M, Block S: Psychiatric disorders in advanced cancer, *Cancer* 110:1665, 2007.
bid, Twice a day; *hr,* hour; *hs,* at bedtime; *IM,* intramuscularly; *IV,* intravenously; *PO,* orally; *PR,* rectally; *prn,* as needed; *q,* every; *qhs,* at every bedtime; *tid,* three times a day.

meaning and areas of accomplishment in them. A variety of models of therapy are used, and none has been shown to be superior over the others. The psychostimulants dextroamphetamine and methylphenidate (2.5 to 5 mg, 8 AM and noon; maximum dose 60 mg daily) often act within a few days. The SSRIs are the first choice when immediate onset is not needed because they usually take several weeks to show effect. Useful agents include citalopram (Celexa) and paroxetine (Paxil) (10 mg PO daily initially; maximum 40 mg PO daily); escitalopram (Lexapro) (10 mg PO daily initially; maximum 20 mg PO daily); sertraline (Zoloft) (50 mg PO daily initially, maximum 200 mg PO daily); fluoxetine (5 to 10 mg PO daily initially; maximum 60 mg PO daily); and venlafaxine (Effexor) (37.5 mg PO twice daily initially; maximum 225 mg PO daily). Venlafaxine inhibits norepinephrine, serotonin, and dopamine reuptake. Major side effects of the SSRIs include hyponatremia, sexual dysfunction or loss of libido, and gastrointestinal complaints (e.g., nausea, diarrhea, and foul-smelling flatus). Modafinil may also be an effective adjuvant agent to reduce SSRI-related sedation. The exact mechanism of action of mirtazapine (Remeron) (15 mg PO at bedtime initially; maximum 45 mg PO at bedtime) is unknown.

If the patient is expected to live longer than weeks to a few months, a stimulant and an SSRI should be started simultaneously, and the stimulant can be titrated off several weeks later. Tricyclic antidepressants are less useful in these patients because of their side-effect profile.

If the patient does not respond to first-line agents, a psychiatrist should be consulted. Referral to a psychiatrist is also necessary when the physician is unsure of the diagnosis; the patient is psychotic, confused, or delirious; the patient previously had a major psychiatric disorder; the patient is suicidal or requesting assisted suicide; or there are dysfunctional family dynamics.

Delirium

Delirium occurs in up to 80% of dying patients and can cause distress and anxiety in caregivers.[26] Delirious patients can be agitated, hypoactive, or vacillate between the two. Symptoms of delirium include insomnia and daytime somnolence, nightmares, restlessness or agitation, irritability, distractibility, hypersensitivity to light and sound, anxiety, difficulty in concentrating or marshaling thoughts, fleeting illusions, hallucinations and delusions, emotional lability, attention deficits, and memory disturbances.

Validated delirium screening and severity tools are available, but a comprehensive psychiatric evaluation is recommended to exclude other disorders, such as anxiety, minor depression, anger, dementia, or psychosis. The cause of delirium is often never determined and often multifactorial. Medications, especially opioids, nonsteroidal antiinflammatory drugs, and high-dose corticosteroids, often contribute. Opioid-induced central nervous system toxicities are more common in patients with renal dysfunction, on high doses of opioids for long periods of time, with impaired cognition before starting the opioids, with dehydration, or taking other psychoactive drugs. Other causes include metabolic abnormalities (hypercalcemia, hyperglycemia, or uremia), malnutrition, hypoxia, fever, infection, uncontrolled pain, hepatic failure, primary brain tumor, and brain metastases.

Treatment for delirium should begin while the underlying cause(s) are being treated. In addition to the medications listed in Table 93-3, it is helpful to make the patient's surroundings as familiar as possible, restore aids to hearing and sight if they are needed, reorient the patient frequently, and have family members, friends, or well-known caregivers present.

MANAGEMENT CONCERNS DURING THE LAST DAYS OF LIFE

For some families, there is the possibility of planning ahead and choosing a setting for their child's death—home, hospice, or hospital. The child may express a preference about where he or she feels safe or prefers to be. Clear information about how the child is likely to die and professional support to validate the family's choice are crucial. Even more important is the explicitly stated "permission" from all

Table 93-4 Treatment of Problems at the End of Life

Problem	Agent(s)	Routes, Doses
Baseline pain	Morphine, hydromorphone, oxycodone SL oral concentrates, subcutaneous infusions	Scheduled; individualized
	Fentanyl transdermal	Scheduled; individualized
Breakthrough pain	Concentrated oxycodone or morphine solutions	Intermittent; individualized
"Death rattle"	Scopolamine	Transderm Scop patch 1-3 q 3 days; gel
	Hyoscyamine	0.125-0.25 SL tid to qid
	Glycopyrrolate	0.1-0.2 mg IV tid to qid
Dyspnea (anxiety)	Lorazepam	1 mg PO, SL, q 2-4 hr
Dyspnea (other)	Morphine/oxycodone	5-10 mg SL oral concentrate q 2 hr
	Morphine	2-4 mg IV q 1 hr
	Chlorpromazine	25-50 mg PO, PR q 4-12 hr
Nausea	Combinations of lorazepam, metoclopramide, dexamethasone, and/or haloperidol	PR q 6 hr; compounded suppositories with desired agents (depending on presumed cause of nausea)
Anxiety	Lorazepam	1 mg PO, SL, q 2-4 hr

members of the professional team that the family may change their choice freely at any time—that all options remain open and that no decision is irrevocable. Although in the current zeitgeist there is strong advocacy for children to die at home, professionals must bear in mind that for some children and families, the hospital is a better option, and that choice must be respected. In the past, siblings were rarely included in these discussions and were often inadequately prepared for the eventuality of a child dying at home. It is only recently that their voices are beginning to be heard.

The Dying Child

Therapist: Are you in any pain? Does anything hurt?
Child: My heart.
Therapist: Your heart?
Child: My heart is broken. I miss everybody.[31]

The distillation of anticipatory grief to its essence marks the imminence of death. At times imperceptibly, at other times dramatically, the child who has been living with the illness is transformed into a dying child.

The end point of the terminal phase is often marked by a turning inward on the part of the child, a pulling back from the external world. Cognitive and emotional horizons narrow, because all energy is needed simply for physical survival. A generalized irritability is not uncommon. The child may talk very little and may even retreat from physical contact. Although such withdrawal is not universal, a certain degree of quietness is almost always evident. The child is pulling into himself or herself, not away from others. This behavior is a normal and expectable precursor to death—a form of preparation for the ultimate separation that lies ahead.[1]

Adults

Physical symptoms that occur in the last week to days before an adult's death include pain, 70%; noisy or moist breathing, restlessness/agitation/delirium, 60%; urinary incontinence or retention, 50%; dyspnea, 20%; and nausea and vomiting, 10%.[26] Patients may also experience fatigue. Hunger and thirst are unusual. Treatments for problems at the end of life are reviewed in Table 93-4. Patient and family wishes and options about the setting for end-of-life care should be explored. Some evidence suggests that patients with cancer who die at home have better quality of life, and their caregivers have better bereavement outcomes than cancer patients who die in the hospital.

Table 93-5 Hospice Services

PERSONNEL

Medical director, nurses, social workers, home health aides, chaplains, volunteers, administrative personnel, medical consultants, occupational therapists, physical therapists, speech therapists, and bereavement counselors.

ITEMS NEEDED FOR PALLIATION OF TERMINAL ILLNESS

Prescription medications
Durable medical equipment and supplies
Oxygen
Laboratory and diagnostic procedures
Radiation and chemotherapy
Transportation when medically necessary for changes in level of care (i.e., inpatient or "respite" in nursing home)

HOSPICE PROGRAMS

In the United States, most hospice care takes place in the home, although patients can be admitted to nursing homes for brief periods (usually 5 days) to provide a respite for the family caregivers, or to the hospital (usually for up to 14 days) if symptoms cannot be controlled at home. Early referral to hospice improves outcomes, and in many cases hospice is the only effective way to support these patients and families at home at the end of life. The Medicare Hospice Benefit does not require a DNR status, but it does require that the attending physician and the hospice medical director certify that the patient has a prognosis of 6 months or less to live if the disease follows its usual course. Medicare reimburses hospice programs about $150 per day per patient (as of fiscal year 2012) to provide the routine care described in Table 93-5. Therefore the cost of transfusions typically required for many patients with hematologic malignancies, even at the end of life, may make it difficult for hospice programs to enroll patients insured by Medicare alone. Other insurance programs, thankfully, often will allow their patients to receive transfusions and hospice care. Notably, many children are not referred to hospice because their illness

experience is inconsistent with hospice specifications—prognosis is uncertain; there is a blending of goals, which can result in more costly health care; and providers lack pediatric expertise. Importantly, the Patient Protection and Affordable Care Act now requires state Medicaid programs to allow children with a life-limiting illness to receive both hospice care and curative treatments concurrently; the full effect of this change remains to be uncovered.

BEREAVEMENT

Bereavement follow-up by the professional team is an intrinsic component of comprehensive pediatric palliative care. Bereaved families often express the sentiment of a double loss: loss of their child and loss of their professional "family"—the treatment team whom they have known and trusted, often over months and years.[2] Parental grief has been recognized as more intense and longer lasting than other types of grief. Contact from a team member after the child's death not only assuages the family's sense of abandonment; the palliative care team can serve a crucial preventive role by identifying families at particular risk and identifying resources for them.[30]

Each bereaved person's loss is unique, but many people manifest similar symptoms of grief, some of which become less persistent as they rebuild their lives. Recurrent intense symptoms typically occur at the anniversary of the death of the patient but can occur at unpredictable times, induced by reminders of the deceased. Just as in the patients described under Anxiety and Grieving, survivors' grief must be differentiated from depression. Survivors appreciate calls or letters from the patient's physician and nurses. For patients enrolled in hospice, a formal bereavement program is offered for the family throughout the first year after the patient's death. After the formal program ends, the bereaved are welcome to continue to participate in any bereavement activities that have been meaningful to them.

At the time of death, survivors may seem numb, confused, or dazed and experience disbelief. By the second month after the death, yearning has replaced disbelief. During the next months, disbelief, depressed mood, and yearning decline gradually, and by 6 months after the death, most people will have accepted the reality of the death and are beginning to think about reengaging in relationships and work, discovering new meaning and purpose. By a year or two, most survivors have accommodated to their loss. They become aware of the changes that must be made if they are to resume old relationships and responsibilities or to establish new ones and risk recurrent loss.

About 10% to 20% of survivors, however, suffer either from depression and/or from a symptom complex previously called *complicated grief,* now identified as *prolonged grief disorder.* Patients with depression manifest symptoms of sadness, anhedonia, and psychomotor retardation, but they are not yearning for the deceased or unable to accept the death. Depressed survivors benefit from counseling and consideration of pharmacologic treatment. Patients with prolonged grief disorder, in contrast, have grief symptoms that last beyond 6 months and cause functional impairments. Such patients are at increased risk for medical and psychiatric illness and should be referred for psychiatric or spiritual counseling. Persons at higher risk for this disorder include those with a history of attachment disorders (childhood abuse, childhood separation anxiety), aversion to lifestyle changes, and being unprepared for the death and unsupported after it. Additional risks include a "dependent, close, confiding" relationship with the deceased. Unfortunately, although there is no randomized controlled trial of a pharmacotherapy that is effective for the extreme grief symptoms, there is a novel effective psychotherapy developed specifically for this disorder that is superior to standard interpersonal psychotherapy.[26]

INTERDISCIPLINARY TREATMENT TEAM

Thank you for giving me aliveness.

— (6-year-old child)[1]

Palliative care demands the combined expertise of an interdisciplinary treatment team to address medical, psychologic, social, and spiritual concerns of the child, siblings, parents, and close family. This knowledge-based expertise must be provided within a context of ongoing accessibility and availability to the family, granting them a sense of the team's abiding presence.

Yet, even while providing this steady care for the patient and family, professional caregivers are often experiencing their own distress in a sort of parallel process. The professional often feels anguish and helplessness in witnessing a child endure pain and suffering—physical or psychic. He or she often identifies with the parents of the child. This reaction intensifies when the caregiver is also a parent, especially if his or her healthy child is the same age as the patient. For the caregiver who does not yet have children, the specter of a fatally ill child may loom threateningly. In surveys, medical and nursing staff often cite the personal pain of losing a child as the most difficult experience in their work with dying children. Special attention should be paid to the grief experienced by trainees with little previous experience with death and dying. Interns are in special need of emotional support following a patient's death. Reviewing each death on the next morning's rounds provides the needed debriefing and shows respect for the patient who has died. When possible and it feels appropriate, clinicians can write a card or attend the funeral or memorial service, which may facilitate closure.

For all these reasons, the professionals who engage in this extraordinarily rich and demanding work articulate significant needs for support themselves. Otherwise, the toll of cumulative unresolved grief exacts a heavy toll in their personal and professional lives. A cohesive team and/or the opportunity for individual and group consultation are crucial for those who are intimately engaged in repeated cycles of attachment.

CHAPTER 94

LATE COMPLICATIONS OF HEMATOLOGIC DISEASES AND THEIR THERAPIES

Wendy Landier and Smita Bhatia

There has been a marked improvement in survival for patients with hematologic malignancies over the past three decades. Currently the population of long-term cancer survivors continues to grow; for patients with hematologic malignancies, the 5-year survival is as follows: adult leukemia, 55%; childhood acute lymphoblastic leukemia (ALL), 89%; childhood acute myeloid leukemia (AML), 61%; adult Hodgkin lymphoma (HL), 87%; childhood HL, 96%; adult non-Hodgkin lymphoma (NHL), 69%; and childhood NHL, 87%.[1] It is estimated that there are 11.9 million cancer survivors in the United States, and approximately 952,000 (8%) of these are survivors of hematologic malignancies.[2]

With this success comes the need to consider the long-term morbidity and mortality associated with the treatments responsible for that improvement in survival. The subject of long-term morbidity suffered by cancer survivors has been the topic of numerous reviews.[3-10] To varying degrees, it has been shown that disease- or treatment-specific subgroups of long-term survivors are at risk for developing adverse outcomes, including premature death, second neoplasms, organ dysfunction (e.g., cardiac, pulmonary, gonadal), reduced growth, decreased fertility, impaired intellectual function, difficulties obtaining employment and insurance, and overall reduced quality of life.

Hematopoietic cell transplantation (HCT) is the treatment of choice for patients with hematologic malignancies experiencing disease recurrence after conventional regimens and for those with disease characteristics associated with poor prognosis if treated with conventional chemotherapy and radiation regimens. Complications observed after HCT often have a multifactorial origin encompassing issues related to prior cancer therapy, intensity of the preparative regimen, graft-versus-host disease (GVHD), and other posttransplantation complications.[11-18]

This chapter summarizes select adverse outcomes among individuals treated for hematologic malignancies with conventional therapy alone or with HCT. Recommendations for providing ongoing follow-up care to this population of survivors are also reviewed.

CARDIAC EFFECTS

Anthracyclines are well-known causes of late-onset cardiomyopathy, characterized by increased afterload followed by development of a dilated, thin-walled left ventricle, which eventually becomes poorly compliant. A review of 30 published studies determined that the prevalence of clinically detected anthracycline-related congestive heart failure among survivors treated for cancer during childhood ranged from 0% to 16%.[19] The incidence of anthracycline-induced cardiomyopathy, which is dose dependent, may exceed 30% among survivors who received cumulative doses in excess of 600 mg/m^2.[20] Among children, this report indicated that a cumulative anthracycline dose exceeding 300 mg/m^2 is associated with an 11-fold increased risk for clinical heart failure, compared with a cumulative dose of less than 300 mg/m^2, with the estimated risk for clinical heart failure increasing with time from exposure.[20] Mulrooney et al[21] used the resources offered by the Childhood Cancer Survivor Study and demonstrated that survivors were 5.9 times more likely to report congestive heart failure. Exposure to 250 mg/m^2 or more of anthracyclines and cardiac radiation exposure of 1500 cGy or more increased the relative hazard of congestive heart failure. More recently, a large case-control study from the Children's Oncology Group demonstrates that cumulative anthracycline exposure as low as 101 to 150 mg/m^2 may be associated with a 3.9-fold increased risk for cardiomyopathy.[22]

The incidence of subclinical anthracycline-related myocardial damage has been the subject of considerable interest. A review of the literature on subclinical cardiotoxicity among children treated with an anthracycline found that the reported frequency of subclinical cardiotoxicity varied considerably across the 25 studies reviewed (frequency ranging from 0% to 57%).[19] Steinherz et al[23] reported that 23% of 201 patients who had received a median doxorubicin cumulative dose of 450 mg/m^2 had echocardiographic abnormalities a median of 7 years after therapy. In a group of childhood leukemia survivors who received a median doxorubicin cumulative dose of 334 mg/m^2, progressive elevation of afterload or depression of left ventricular contractility was present in approximately 57% of patients.[24] Because of marked differences in the definition of outcomes for subclinical cardiotoxicity and because of the heterogeneity of the patient populations investigated, it is difficult to accurately evaluate the potential long-term outcomes within anthracycline-exposed patient populations with subclinical findings.

Among anthracycline-exposed patients, the risk for cardiotoxicity can be increased by mediastinal irradiation,[25] uncontrolled hypertension,[26,27] underlying cardiac abnormalities,[28] exposure to chemotherapeutic agents other than anthracyclines (such as cyclophosphamide, dactinomycin, mitomycin C, dacarbazine, vincristine, bleomycin, and methotrexate),[27,29,30] and electrolyte imbalances such as hypokalemia and hypomagnesemia.[31] Risk is also increased for survivors who are female,[32] African American,[33] and those who were very young (<5 years old) at the time of therapy.[34]

Chronic cardiac toxicity associated with radiation alone most often manifests as valvular abnormalities, coronary artery disease, pericardial effusions, or constrictive pericarditis, sometimes in association with pancarditis. This risk is associated with radiation dose and volume and is lifelong; absolute risk increases with length of time since exposure.[35] Although a dose of 40 Gy of total heart irradiation appears to be the usual threshold, pericarditis has been reported after as little as 15 Gy, even in the absence of radiomimetic chemotherapy.[36] Symptomatic pericarditis, which usually develops 10 to 30 years after irradiation, is found in 2% to 10% of patients.[37] Subclinical pericardial and myocardial damage, as well as valvular thickening, may be common in this population.[38] Coronary artery disease has also been reported after radiation to the mediastinum.[39]

HCT recipients are at an increased risk for cardiovascular complications. In allogeneic HCT recipients, risk for premature death resulting from cardiac complications was 2.3-fold that of the U.S. general population.[40] A recent study reported the incidence of coronary artery disease after allogeneic HCT to be 2.2%. Coronary artery disease was the cause of death for 5% of the 60 patients who died in the study population.[41] Tichelli et al[42] described the cumulative incidence and risk factors for cardiovascular events among allogeneic and autologous HCT recipients. The 15-year cumulative incidence of cardiovascular

events (coronary artery disease, stroke, and peripheral vascular disease) after allogeneic HCT was 7.5% compared with 2.3% after autologous HCT. Adjusting for age, the risk for cardiovascular event was sevenfold higher among allogeneic HCT recipients, when compared with autologous HCT recipients. Increasing age at HCT was also associated with an increased risk; thus the 20-year cumulative incidence of cardiovascular event was 8.7% for those transplanted at less than 20 years of age; it was 20.2% for those transplanted between 20 and 40 years; and finally it was 50% among those transplanted at ages 40 to 60 years.

Late cardiac dysfunction after HCT is multifactorial in origin. Factors that may increase the risk for its development include pre-HCT therapy with anthracyclines, chest radiation, total body irradiation (TBI), and post-HCT therapeutic exposures to cardiotoxic agents. In addition, there is now increasing evidence that presence of the conventional cardiovascular risk factors (hypertension, diabetes, dyslipidemia, increased body mass index [BMI], physical inactivity, and smoking) could increase the risk for cardiac toxicity in patients already exposed to cardiotoxic agents. Armenian et al[43] used a nested case-control design to examine the independent role of pre-HCT therapeutic exposures, transplantation-related conditioning, and comorbidities (pre- and post-HCT) in the development of late congestive heart failure after HCT. The authors found that anthracycline dose greater than 250 mg/m^2 and two or more cardiovascular risk factors post-HCT were independently associated with an increased risk for late congestive heart failure.[43] Tichelli et al[44] reported the cumulative incidence of first arterial events to be 6% at 15 years after HCT. When patients were stratified by number of cardiovascular risk factors, cumulative incidence of cardiovascular events increased to 17% for those with three or more risk factors, versus 4% for those with two or fewer risk factors. In another report, Armenian et al[45] used a nested case-control study design to identify clinical and treatment-related risk factors for development of late (1+ years after HCT) cardiovascular disease. The authors found the presence of multiple cardiovascular risk factors (two or more of the following: obesity, dyslipidemia, hypertension, and diabetes) after HCT to be associated with a 5.2-fold increased risk for late cardiovascular disease. Furthermore, pre-HCT chest radiation was associated with a ninefold increased risk for coronary artery disease.

Thus HCT recipients are at increased risk for cardiovascular complications, and traditional cardiovascular risk factors are important in modifying that risk. Estimates of dyslipidemia in different cohorts who survived at least 1 year after allogeneic HCT range from 8.9%[41] to 56% (71% of these patients were on immunosuppressive therapy).[46] The presence or absence of ongoing immunosuppressive therapy in allogeneic HCT patients may account for some of the differences in reported risk factor incidence. The Bone Marrow Transplant Survivor Study ascertained the prevalence of self-reported late occurrence of cardiovascular risk factors, in particular, diabetes and hypertension in 1089 HCT survivors, who were not taking immunosuppressants at the time of study participation. Allogeneic HCT recipients were 3.65 times more likely to report diabetes than siblings and 2.06 times more likely to report hypertension compared with siblings. Allogeneic HCT recipients were also 2.3 times more likely than autologous HCT recipients to develop hypertension. TBI was associated with an increased risk for diabetes. This study demonstrated that allogeneic HCT survivors have a higher age- and BMI-adjusted risk for diabetes and hypertension, potentially leading to a higher-than-expected risk for cardiovascular events with age.[47]

Given the known acute and long-term cardiac complications of cancer therapy, prevention of cardiotoxicity is a focus of active investigation. Previous reports have suggested that doxorubicin-induced cardiotoxicity can be prevented by continuous infusion of the drug.[48-50] Lipshultz et al[51] compared cardiac outcomes in children with leukemia receiving bolus or continuous infusion doxorubicin and reported that continuous doxorubicin infusion over 48 hours did not offer a cardioprotective advantage over bolus infusion. Both regimens were associated with progressive subclinical cardiotoxicity. Several other studies have reported no statistically significant difference in echocardiographic characteristics of children with cancer 5 to 7 years after treatment with either continuous infusion (over 6 to 24 hours) or bolus infusion of anthracyclines.[52,53]

Liposome-encapsulated anthracyclines have been explored for their propensity to result in a lower incidence of cardiotoxicity. The premise behind this theory is as follows: liposome-encapsulated anthracyclines escape the capillaries with wide endothelial gaps in the tumor, thus reaching high concentrations in the interstitial fluid of the tumor bed. On the other hand, they are less likely to escape the tight capillary junctions of the heart. Biopsy results have confirmed a low early cardiotoxicity[54] and the relative safety in clinical use.[55]

Agents such as dexrazoxane, which remove iron from anthracyclines, have been investigated as cardioprotectants. Clinical trials of dexrazoxane have been conducted, with encouraging evidence of short-term cardioprotection among children.[56] In a study of 206 children with ALL who were randomly assigned to receive doxorubicin with or without dexrazoxane, Lipshultz et al[57] demonstrated that patients treated with doxorubicin alone were significantly more likely to have elevated troponin T levels, indicative of myocardial injury, than those who received doxorubicin with dexrazoxane. There was no difference in event-free survival at 2.5 years between the two arms. A recent follow-up report of this group at a median of 8.7 years found that event-free survival did not differ significantly between the two groups, and that the risk for second malignancies was not increased.[58,59] Serial echocardiographic measurements during the 4 years after this trial revealed that children treated with doxorubicin and dexrazoxane have less left ventricular fractional shortening and greater left ventricular mass and left ventricular wall thickness over time. Also, the cardioprotective effects appear to be sex specific, with females showing the greatest protective effect. However, comprehensive longer-term follow-up is required to document that dexrazoxane does indeed have a cardioprotective effect, while maintaining comparable event-free survival.[60,61]

Specific recommendations for monitoring, based on age and therapeutic exposure, are delineated within the Children's Oncology Group *Long-Term Follow-Up Guidelines*[62] (COG LTFU guidelines) available at http://www.survivorshipguidelines.org. According to these guidelines, patients exposed to anthracyclines need ongoing monitoring for late-onset cardiomyopathy using serial noninvasive testing (echocardiogram) and physical examination. The frequency of echocardiograms can range from yearly to every 5 years, depending on cumulative anthracycline dose, age at exposure, and treatment with mediastinal radiation. Pregnant women previously treated with anthracyclines should be closely monitored, because changes in volume during the third trimester could add significant stress to a potentially compromised myocardium. In addition to monitoring for cardiomyopathy, survivors who received radiation involving the heart field also need monitoring for potential early-onset atherosclerosis. Heart-healthy lifestyles should be encouraged for all survivors, including implementation of a regular exercise program, dietary recommendations, and screening for dyslipidemia. Joint recommendations for monitoring long-term survivors of HCT by the European Group for Blood and Marrow Transplantation/Center for International Blood and Marrow Transplant Research/American Society for Blood and Marrow Transplantation (EBMT/CIBMTR/ASBMT) suggest that at a minimum, cholesterol and high-density-lipoprotein cholesterol (HDL-C) should be checked at least every 5 years for men starting by age 35 years and women starting at age 45. It is suggested that screening for dyslipidemia should start at age 20 for smokers, patients with diabetes, or patients with a family history of heart disease. Abnormalities (total cholesterol >200 mg/dL or HDL-C <40 mg/dL) should be followed up with a full fasting lipoprotein profile.[63]

PULMONARY EFFECTS

Compromise of pulmonary function among survivors of hematologic malignancies has been reported after conventional therapy for HL[64-66]

and leukemia[67,68] and after HCT.[12,13,69] Impairments evident by pulmonary function testing include reductions in total lung capacity (TLC), forced vital capacity (FVC), forced expiratory volume in the first second of expiration (FEV_1), and gas transfer (diffusing capacity of lung for carbon monoxide [DLCO]), suggesting obstructive and restrictive defects. Risk factors include exposure to certain chemotherapeutic agents (particularly bleomycin), radiation to the chest, underlying lung disease, and a younger age at exposure to the pulmonary-toxic therapeutic agents.

Significant late toxicities involving the airway and lung parenchyma, including restrictive and chronic obstructive lung disease and bronchiolitis obliterans, are observed after HCT.[70] Inaba et al[71] measured serial pulmonary function tests before and after HCT at a single institution. The following tests were noted to decline after HCT: FEV_1/FVC, forced midexpiratory flow, TLC, DLCO, residual volume (RV), functional residual capacity, and RV/TLC. Older age at the time of allogeneic HCT was associated with lower FEV_1/FVC, DLCO, and higher RV/TLC. The prognosis is quite dismal, with overall survival of only 13% at 5 years. Bronchiolitis obliterans syndrome is a progressive, insidious lung disease occurring after allogeneic HCT and results in progressive circumferential fibrosis and ultimate cicatrization of the small terminal airways, manifesting as new fixed airflow obstruction (reviewed in Williams et al[72]). Bronchiolitis obliterans has been shown to have a strong correlation with chronic GVHD and has been reported in up to 6% of HCT recipients. Most patients present when the degree of airflow is severe, causing significant dyspnea on exertion and a persistent nonproductive cough. Lung biopsy findings demonstrating damage to the bronchiolar epithelium, obliteration of bronchiolar lumens, inflammation between the epithelium and the smooth muscle, and pulmonary fibrosis are characteristic. The National Institutes of Health definition of bronchiolitis obliterans requires the following: (1) absence of active infection, (2) decreased FEV_1 (<75% of predicted value), (3) evidence of airway obstruction with a ratio of FEV_1 to FVC of less than 0.7, (4) elevated RV of air (>120% of predicted normal), or (5) an expiratory chest computed tomographic (CT) scan or lung biopsy results that reveal air trapping or bronchiectasis. Recommended therapy includes high-dose systemic steroids for a protracted course, with or without the addition of other immunosuppressants. Leukotriene inhibitors have emerged as a potential therapy, because of the elevated levels of leukotrienes implicated in bronchiolitis obliterans.

The COG LTFU guidelines recommend monitoring for pulmonary dysfunction in childhood cancer survivors that includes assessment of symptoms such as chronic cough or dyspnea on annual follow-up. Risks of smoking and exposure to secondhand smoke should be discussed with all patients.[62] The best approach to chronic pulmonary toxicity of anticancer therapy is preventive and includes respecting cumulative dosage restrictions of bleomycin and alkylators, limiting radiation dosage and port sizes, and avoidance of primary or secondhand smoke. Pulmonary function tests and chest x-ray examination are recommended as a baseline upon entry into long-term follow-up for patients at risk, repeated as clinically indicated in symptomatic patients and in those with subclinical abnormalities identified on screening evaluation. Repeat evaluation should also be considered for at-risk patients before general anesthesia. Influenza and pneumococcal vaccines are encouraged in survivors at risk for pulmonary compromise. Joint recommendations for monitoring long-term survivors of HCT by the EBMT/CIBMTR/ASBMT suggest routine clinical assessment at 6 months, 1 year, and annually thereafter; institution of active smoking cessation programs; and pulmonary function tests and focused radiologic assessment at 1 year after allogeneic HCT for patients with signs or symptoms of lung compromise or earlier as clinically indicated. Annual testing is recommended thereafter for patients with recognized defects or appropriate clinical circumstances. For autologous HCT recipients, pulmonary function testing should be performed for those with known deficits before HCT or with those exposed to radiation or other pulmonary toxic agents during or after transplantation. Chest radiographic studies are indicated based on symptoms or abnormal pulmonary function test results.[63]

ENDOCRINOLOGIC EFFECTS

Thyroid

Patients with hematologic malignancies treated with cranial, craniospinal, or mantle irradiation are at increased risk for thyroid complications. Among survivors of HL, and to a lesser extent leukemia, abnormalities of the thyroid gland, including hypothyroidism, hyperthyroidism, and thyroid neoplasms, have been reported to occur at rates significantly higher than those found in the general population.[73-75] Hypothyroidism is the most common nonmalignant late effect involving the thyroid gland. After exposure to radiation at doses above 15 Gy, laboratory evidence of primary hypothyroidism is evident in 40% to 90% of patients with HL and NHL.[74,76,77]

In an analysis of 1791 5-year survivors of pediatric HL (median age at follow-up, 30 years), Sklar et al[73] reported the occurrence of at least one thyroid abnormality in 34% of subjects. The risk for hypothyroidism was increased 17-fold compared with sibling controls; increasing dose of radiation, older age at diagnosis of HL, and female sex were identified to be significant independent predictors of increased risk. The actuarial risk for hypothyroidism for subjects treated with 45 Gy or more was 50% at 20 years after diagnosis of HL. Hyperthyroidism was reported to occur in only 5%.

In another large cohort of 1677 patients with HL treated at Stanford University Hospital between 1961 and 1989 with irradiation involving the thyroid (mean age at diagnosis, 28 years; mean duration of follow-up, 9.9 years), the actuarial risk for developing thyroid disease was 52% at 20 years and 67% at 26 years after treatment. In this population, the actuarial risk for developing overt or subclinical hypothyroidism was 44% by 25 years after therapy; the risk for developing thyroid cancer was 1.7% (15.6 times the expected risk).[74]

Most cases of overt hypothyroidism after HCT result from primary hypothyroidism caused by radiation injury. The incidence of hypothyroidism after HCT depends on the type of myeloablative conditioning regimen, ranging from as high as 90% after exposure to single-dose TBI to 10% to over 50% after fractionated TBI.[15,16]

Thyroid nodules are common in patients treated with neck radiation for HL, but the majority of these do not undergo malignant transformation.[78,79] In a study of 647 children treated for HL, 67 developed thyroid nodules during or after therapy (median time between diagnosis of HL and thyroid nodule was 10.5 years with a range of 0.2 to 24.8 years). All but one of these patients had received neck radiation as part of their therapy, with a median dose to the thyroid of 35 Gy. Seven (10%) of the 67 nodules were malignant.[78]

Growth

Poor linear growth and short adult stature are common complications after successful treatment of hematologic malignancies in childhood. The adverse impact of central nervous system (CNS) irradiation on adult final height among childhood leukemia patients has been well documented, with final heights below the fifth percentile in 10% to 15% of survivors.[80-83] The effects of cranial irradiation appear to be related to age and sex, with females and children younger than 8 years at the time of therapy being more susceptible.[84,85] The precise mechanisms by which cranial irradiation induces short stature are not clear. Disturbances in growth hormone production have not been found to correlate well with observed growth patterns in these patients.[86,87] The phenomenon of early onset of puberty in girls receiving cranial irradiation may play some role in the reduction of final height.[88,89] In childhood, leukemia survivors not treated with cranial irradiation, there are conflicting results regarding the impact of chemotherapy on final height.[81,90]

Impaired linear growth after HCT is likely due to an interaction of multiple factors, including host characteristics (young age), treatment exposures (prior cranial irradiation, TBI), and post-HCT complications, such as chronic GVHD.[16] Findings suggest that final height is unaffected in children who receive busulfan or cyclophosphamide as pretransplant conditioning.[91]

Survivors should be monitored using standardized growth curves until final height is achieved. An endocrine consultation should be obtained for children whose height is less than the third percentile, for those whose height has dipped across two or more percentiles, or whose growth velocity is less than 4 to 5 cm/yr.[85]

Obesity

An increased prevalence of obesity has been reported among survivors of childhood ALL.[92-94] In an analysis from the Childhood Cancer Survivor Study, Oeffinger et al[95] compared the distribution of BMI of 1765 adult survivors of childhood ALL with that of 2565 adult siblings of childhood cancer survivors. Survivors were significantly more likely to be overweight (BMI of 25 to <30) or obese (BMI ≥30). Risk factors for obesity were cranial irradiation, female sex, and age 0 to 4 years at diagnosis of leukemia. Females diagnosed under the age of 4 years who received a cranial radiation dose of more than 20 Gy were found to have a 3.8-fold increased risk for obesity. Obesity has the potential to adversely impact the overall health status in survivors and is associated with insulin resistance, diabetes mellitus, hypertension, and dyslipidemia. Growth hormone deficiency related to cranial radiation may predispose adult survivors of childhood ALL, particularly females, to abdominal obesity[96] and metabolic syndrome.[97]

Gonadal Dysfunction

Treatment-related gonadal dysfunction has been well documented in male and female patients after therapy for hematologic malignancies, and there is a reasonable body of research that provides a basis for counseling patients regarding the long-term gonadal effects of radiation and chemotherapy.

Radiation effects on the ovary are age and dose dependent. It has been estimated that there is a 50% depletion in oocytes after exposure of the ovaries to 2 Gy.[98] Amenorrhea develops in approximately 68% of prepubescent females treated for HL with ovarian doses of 12 to 15 Gy, whereas 100% of adult females older than 40 years of age will sustain irreversible ovarian failure after doses of 4 to 7 Gy.[99] Spinal irradiation for the treatment of childhood leukemia appears to result in clinically significant ovarian damage in some survivors,[100] and cranial irradiation in young girls is associated with an increased risk for premature puberty.[101]

The effects of radiation on testicular function, including germ cell number and Leydig cell function, have been investigated. Reduced sperm production has been observed after testicular doses of 1 to 6 Gy and follows a dose-dependent pattern.[102] Azoospermia has been reported among HL patients with calculated testicular irradiation exposures ranging from 1 to 3 Gy.[103] Testicular doses between 4 and 6 Gy have been associated with prolonged azoospermia and decreased testicular volume.[104] The limited data on the long-term outcomes of very young males treated for HL suggest germ cell effects similar to those seen in older HL patients.[105] Leydig cells, although also affected by radiation in a dose-dependent fashion, require higher exposure levels to sustain damage than those seen for the germ cells.[106] Testicular dose of 24 Gy among prepubertal males have been reported to be associated with delayed pubertal development and abnormal testosterone and gonadotropin levels.[107-109]

Ovarian and testicular damage can also result from chemotherapeutic agents, with alkylating agents showing the strongest association. Effects of chemotherapy on gonadal function are typically sex-, age-, and dose-dependent. The ovaries tend to be less sensitive to the effects of alkylating agent exposure, compared with the testes. Ovarian dysfunction has been well documented in HL patients treated with alkylating agents, singly or in combination (e.g., MOPP regimen consisting of mechlorethamine, vincristine [Oncovin], procarbazine, and prednisolone or a COPP regimen consisting of cyclophosphamide, vincristine [Oncovin], procarbazine, and prednisolone).[105,110-112] MOPP and COPP regimens have been reported to result in azoospermia in more than 90% of exposed males.[113] Even with a reduction in the dose of cyclophosphamide in the hybrid COPP/Adriamycin, bleomycin, and vinblastine (ABV) regimen for HL, the majority of young males are infertile, likely due to the procarbazine component in this regimen.[114] In a study of 6224 male survivors of childhood cancer between ages 15 and 44, those with a diagnosis of hematologic malignancy were significantly less likely to sire a pregnancy compared to sibling controls; those with a diagnosis of HL were least likely to sire a pregnancy (relative risk [RR] of fertility, 0.34; 95% confidence interval [CI], 0.28 to 0.41), followed by NHL (RR, 0.60; 95% CI, 0.48 to 0.74), and leukemia (RR, 0.70; 95% CI, 0.59 to 0.84); P <.001 for all comparisons.[115]

Young boys and adolescent males with aplastic anemia who receive standard-dose cyclophosphamide alone (200 mg/kg) as the pretransplant conditioning regimen appear to retain normal Leydig cell function, as do males who receive busulfan and cyclophosphamide, with normal plasma concentrations of luteinizing hormone and testosterone and normal progression through puberty.[16] Evidence of germ cell damage can occur and is more likely among patients treated after puberty.[116] Semen analyses have been normal in approximately two-thirds of men after high-dose cyclophosphamide, and several men have fathered normal children. Men treated with TBI-based regimens who have not received prior testicular irradiation generally retain normal Leydig cell function, regardless of their age at treatment.[116] Germ cell dysfunction occurs in all men treated with TBI-based regimens, and azoospermia is the rule.

Female patients treated with high-dose cyclophosphamide alone retain normal ovarian function, regardless of age at exposure, although these subjects may be at an increased risk for early menopause as they reach the third decade of life.[117] These individuals can sustain a normal pregnancy resulting in normal offspring. Females treated with busulfan and cyclophosphamide are at very high risks for ovarian failure and premature menopause.[118] The outcome of ovarian function after TBI appears to be determined by the age at exposure. Approximately 50% of prepubertal girls receiving fractionated TBI enter puberty spontaneously, and premature ovarian failure is seen in all patients who are older than 10 years of age when treated with TBI.[16] Pregnancies among survivors of TBI are at an increased risk for spontaneous abortion.[119]

Pregnancy Outcomes

Offspring of survivors of childhood hematologic malignancies do not appear to be at increased risks for cancer or congenital malformations.[120] In a study of 593 adult survivors of childhood ALL, 15.7% (93 of 593) of survivors (mean age, 22.6 years) had given birth to or fathered a total of 140 live-born offspring, compared with 29.8% (122 of 409) of sibling controls (mean age, 25.2 years). There was no significant difference in the rate of birth defects between offspring of survivors (3.6% [5 of 140]) versus sibling controls (3.5% [8 of 228]) (RR, 1.02; 95% CI, 0.34 to 3.05).[121] In a recent review of pregnancy outcomes of participants in the Childhood Cancer Survivor Study,[112] the offspring of survivors were more likely to be premature (born before 37 weeks' gestation) compared with the survivors' female siblings (odds ratio [OR], 1.9; 95% CI, 1.4 to 2.4; P <.001); and the offspring of women who received uterine radiation at a dose of more than 5 Gy were more likely to be small for gestational age (OR, 4.0; 95% CI, 1.6 to 9.8; P = .003). The frequency of premature birth was not related to prior maternal exposure to alkylating agents, but prior exposure to doxorubicin or daunorubicin increased the risk for low birth weight independent of pelvic irradiation history.[112] There were no significantly increased rates of congenital or chromosomal anomalies in the offspring of survivors compared with siblings.[112]

MUSCULOSKELETAL EFFECTS

Osteonecrosis is a painful and debilitating condition that develops when the blood supply to the bone is disrupted, usually in areas of

terminal circulation. The condition is believed to be the result of vascular compromise with resultant death of bone and cell tissues or disruption of bone repair mechanisms.[122,123] Osteonecrosis has been reported after conventional therapy for hematologic malignancies, particularly after exposure to dexamethasone between the ages of 10 and 20 years. This complication usually develops during or shortly after completion of therapy but may progress over time.[124-126] Mattano et al[124] described the magnitude of risk and associated risk factors for development of osteonecrosis in children with ALL treated on Children's Oncology Group therapeutic protocols. The cumulative incidence was 9.3% at 3 years; the incidence was higher in older patients (14.2% for patients ≥10 years of age versus 0.9% for patients <10 years of age), and higher among whites than African Americans. Furthermore, the incidence was higher among patients randomized to receive two 21-day dexamethasone courses versus one course.

Osteonecrosis is increasingly being reported among HCT recipients.[127-129] Campbell et al[130] conducted a retrospective cohort study and described the cumulative incidence of osteonecrosis to be 2.9% among autologous HCT recipients, 5.4% among allogeneic HCT recipients, and 15% among unrelated-donor HCT recipients. Among allogeneic HCT recipients, male sex, presence of chronic GVHD, and exposure to cyclosporine, tacrolimus (FK506), prednisone, and mycophenolate mofetil (MMF) rendered patients at increased risk, in particular among patients with a history of exposure to three or more drugs. The mean latency period was 18 months. The hip joint was the most commonly involved joint (80%); however, the knee, wrist, and ankle joints were also affected. The cumulative incidence of surgery (mainly arthroplasty) approached 31% at 1 year from osteonecrosis diagnosis.

Osteopenia (bone density 1 to 2.5 standard deviations [SDs] below mean) or osteoporosis (bone density >2.5 SDs below mean) is commonly seen in survivors of hematologic malignancies.[131-133] Risk factors include therapy with corticosteroids, methotrexate (at higher doses), and cranial irradiation with resultant pituitary insufficiency or gonadal dysfunction. Survivors of HCT are also at increased risk for reduced bone mineral density; identified risk factors in these patients include treatment with corticosteroids for chronic GVHD, prior cranial irradiation (resulting in growth hormone deficiency), and gonadal failure.[16] Lifestyle factors that increase the risk for osteopenia include lack of regular weight-bearing exercise, inadequate calcium and vitamin D intake, smoking, and excessive alcohol consumption.[134,135]

Detection and diagnosis of musculoskeletal sequelae depend largely on anticipating these issues in vulnerable hosts, on taking a careful history, and on performing a thorough physical examination. Pain or a history of fractures may be the only indication of osteonecrosis or osteoporosis. Because of progress with various interventions (including the use of calcium supplementation, calcitonin, bisphosphonates, and hormone replacement in patients with gonadal failure), the COG LTFU guidelines recommend a baseline dual-energy x-ray absorptiometry (DEXA) or quantitative CT scan for survivors 2 or more years following completion of treatment, with repeat studies as clinically indicated.[62] Joint recommendations for monitoring long-term survivors of HCT by the EBMT/CIBMTR/ASBMT suggest a screening dual photon densitometry performed at 1 year after transplantation in adult women or for any patient who has received prolonged treatment with corticosteroids or calcineurin inhibitors.[63] Screening for osteonecrosis is not recommended; however, clinicians should maintain a high level of suspicion for patients with exposure to irradiation or prolonged corticosteroids.

NEUROCOGNITIVE EFFECTS

Among survivors of childhood leukemia, neurocognitive late effects represent one of the more intensively studied topics.[136-139] Early curative regimens for childhood ALL relied heavily on cranial irradiation, usually in doses of 24 Gy.[136] Results from studies of neurocognitive outcomes in early populations of ALL survivors (particularly in younger children) are directly responsible for the marked reduction in the use of cranial irradiation, which is currently reserved for the treatment of very high-risk subgroups or patients with CNS involvement. For the majority of children with ALL, CNS prophylaxis consists of either intrathecal methotrexate or triple intrathecals (i.e., methotrexate, cytosine arabinoside, and hydrocortisone). Kadan-Lottick et al[140] evaluated the neurocognitive function in children with ALL randomized to receive intrathecal methotrexate or intrathecal triples. The two groups performed similarly on tests of full-scale intelligence quotient (IQ), academic achievement, attention/concentration, memory, and visual/motor integration. The study did not show any clinically meaningful differences in neurocognitive functioning between patients previously randomly assigned to intrathecal methotrexate or triple intrathecals. Dexamethasone has been shown to result in better event-free survival than prednisone, presumably due to higher CNS penetration. Kadan-Lottick et al[141] compared the neurocognitive function in children previously randomized to dexamethasone or prednisone in the treatment of childhood ALL. There were no group differences in the distribution of test scores or the parents' report of neurologic complications, psychotropic drug use, and special education.

Neurocognitive deficits, as a general rule, usually become evident within several years after CNS-directed therapy and tend to be progressive in nature. Leukemia survivors treated at a younger age (i.e., less than 6 years of age) may experience significant declines in IQ scores.[142] However, reductions in IQ scores are typically not global but rather reflect specific areas of impairment, such as attention and other nonverbal cognitive processing skills.[143,144] Affected patients may experience information-processing deficits resulting in academic difficulties. These patients are particularly prone to problems with receptive and expressive language, attention, and visual and perceptual motor skills, most often manifested as academic difficulties in the areas of reading, language, and mathematics. Assessment of educational needs and subsequent educational attainment have demonstrated that survivors of childhood leukemia are significantly more likely to require special educational assistance but have a high likelihood of successfully completing high school if they receive appropriate educational services.[145,146] Chemotherapy- or radiation-induced destruction of normal white matter partially explains intellectual and academic achievement deficits.[147] The pathogenesis of CNS damage is only partially understood; evidence suggests that therapy-related direct effects on intracranial endothelial cells and brain white matter, as well as immunologic mechanisms, play roles.

A spectrum of neuropathologic syndromes related to leukoencephalopathy[148] may occur in survivors of childhood hematologic malignancies, including radionecrosis, necrotizing leukoencephalopathy, mineralizing microangiopathy and dystrophic calcification, cerebellar sclerosis, and spinal cord dysfunction, manifesting clinically as ataxia, spasticity, dysarthria, hemiparesis, or seizures. Imaging abnormalities may or may not be evident in these patients. Leukoencephalopathy has been primarily associated with methotrexate-induced injury of white matter. However, cranial irradiation may play an additive role through disruption of the blood-brain barrier, allowing greater exposure of the brain to systemic therapy. Although some abnormalities have been detected by diagnostic imaging studies, the abnormalities observed have not been well demonstrated to correlate with clinical findings and neurocognitive status.

Many survivors of adult-onset hematologic malignancies also experience impairments of neurocognitive function, including memory loss, distractibility, and difficulty performing multiple tasks. These patients may also concurrently suffer from mood disturbances and symptoms that compromise their ability to function adequately, including fatigue and pain.[149]

HCT survivors are also at risk for neurocognitive late effects. Prospective, longitudinal evaluations of intellectual and adaptive functioning of children receiving a transplant have revealed declines in intellectual function, particularly among those less than 6 years of age at transplantation.[150] Among the adult populations, studies in general have reported good levels of function and well-being in long-term survivors of transplantation, although there are increasing reports of fatigue, lack of energy, and sleep problems, which could

potentially affect cognitive functioning.[151] Syrjala et al[152] used a prospective longitudinal study design to describe neurocognitive function over 5 years after allogeneic HCT for cancer survivors and compared with matched controls. Ninety-two survivors were tested before HCT, after 80 days, and 1 and 5 years after HCT. Sixty-six case-matched controls received testing at the 5-year time point.[152] A global deficit score summarized overall impairment. Survivors recovered significant cognitive function from posttransplantation (80 days) to 5 years in all tests except verbal recall. Between 1 and 5 years, verbal fluency improved, as did executive function, but motor dexterity did not, remaining significantly below population norms. Using the global deficit score, 41.5% of the survivors had mild or greater deficits, a proportion that was significantly higher than that among the controls (17.5%, $P = 0.007$). For additional information see box on Neuropsychologic Sequelae After Hematopoietic Cell Transplantation in Adults.

The COG LTFU guidelines recommend a baseline neuropsychologic evaluation for patients who received therapy that may affect neurocognitive function. This should be repeated as clinically indicated and at key transition points (e.g., transitioning from grade school to middle/high school); an annual assessment of their vocational or educational progress should also be monitored.[62] Joint recommendations for monitoring long-term survivors of HCT by the EBMT/CIBMTR/ASBMT suggest that all recipients of HCT should undergo clinical evaluation for symptoms or signs of neurologic dysfunction at 1 year after HCT. Additional tests such as neuropsychologic testing may be warranted for those with symptoms or signs.[63]

OTHER TOXICITIES

Ocular Effects

Survivors of hematologic malignancies are at risk for the development of cataracts as a consequence of therapy with corticosteroids, cranial irradiation,[153,154] TBI,[155] or busulfan.[156] Hoover et al[154] evaluated 82 ALL survivors, all of whom received treatment with prednisone (3.4 to 10.2 g/m^2/yr) and cranial irradiation (1800 to 2800 cGy). At a mean of 32 months after completion of therapy, 52% of patients had evidence of posterior subcapsular cataracts; however, there was minimal ocular morbidity in this cohort, with median visual acuity of 20/20 in the affected eyes (range, 20/15 to 20/50). Holmstrom et al[156] studied a cohort of 45 children who were followed for 2 to 10 years after HCT, 95% (20 of 21) of children conditioned with TBI and 21% (5 of 24) of children conditioned with busulfan developed cataracts. Belkacemi et al[157] studied 1063 patients who underwent HCT for acute leukemia; the overall 10-year incidence of cataracts in this group of patients was 50%. Single-dose TBI was associated with a 60% incidence of cataracts, and fractionated TBI was associated with a 43% incidence for those receiving six or fewer fractions, and a 7% incidence for those receiving more than six fractions. Factors independently associated with an increased risk for cataract formation in this cohort were older age (>23 years), allogeneic bone marrow transplantation, higher dose rate (>0.04 Gy/min), and steroid administration for longer than 100 days. Xerophthalmia may also occur as a late complication because of decreased lacrimation resulting from damage to the lacrimal gland during radiation or, in HCT patients, from chronic GVHD.[158] Westeneng et al[159] followed 101 adults up to 24 months after allogeneic HCT and reported ocular GVHD in 54% of patients, manifesting mainly as xerophthalmia and conjunctivitis; blepharitis and uveitis were encountered less often. Tabbara et al[160] reported major ocular complications in 13% of 620 patients (age range 9 to 65 years) after allogeneic HCT; complications included chronic ocular GVHD, corneal ulcers, cataracts, glaucoma, cytomegalovirus retinitis, fungal endophthalmitis, and the acquisition of allergic conjunctivitis from atopic donors.

Audiologic Effects

Survivors of hematologic malignancies who received platinum chemotherapy, those who had cranial irradiation at a young age (especially during infancy),[161] and those who required supportive therapy with aminoglycoside antibiotics[162] are at risk for therapy-related hearing loss. Hearing loss associated with ototoxic agents is generally sensorineural in origin and is usually irreversible. Although a low incidence of hearing loss has been reported in survivors of HCT performed in childhood, the risk is elevated threefold to fourfold over that in the general population.[155] Data are beginning to emerge regarding genetic polymorphisms associated with increased susceptibility to platinum-related hearing loss; these data may prove useful in identifying future patients who are at increased risk for hearing loss as a consequence of platinum-based chemotherapy.[163,164]

Dental Effects

Children whose teeth have not completely developed at the time of cancer treatment are most vulnerable to dental complications, and treatment with chemotherapy during early childhood may result in qualitative problems with enamel and root development.[165,166] However, patients of all ages who received radiation therapy involving the head or neck (including cranial irradiation and TBI) are susceptible to dental complications, most often manifesting as increased susceptibility to dental caries and gingivitis as a result of diminished salivary gland function. Patients who have undergone HCT are at increased risks for dental caries, gum disease, and xerostomia[124]; abnormalities of tooth development are seen in survivors who underwent HCT during childhood.[167] Younger age at transplantation (especially under 6 years) and TBI doses above 10 Gy are associated with the greatest risk.[168]

Hepatic Effects

Although acute hepatic dysfunction may be seen with certain chemotherapeutic agents, including antimetabolites and anthracyclines, there has generally been a low reported incidence of delayed hepatotoxicity in patients receiving these agents.[169] However, recent reports of chronic hepatotoxicity and portal hypertension have emerged in survivors of childhood ALL who received 6-thioguanine–based maintenance therapy,[170-173] and these survivors require long-term surveillance for this complication.[174] Chronic viral hepatitis, resulting from transfusion of contaminated blood or serum products, should be considered in the differential diagnosis of all survivors with

Neuropsychologic Sequelae After Hematopoietic Cell Transplantation in Adults

The few studies describing neurocognitive sequelae in adults undergoing hematopoietic cell transplant (HCT) suggest that these patients are at risk for developing adverse sequelae related to neuropsychologic functioning, such as slowed reaction time, reduced attention and concentration, and difficulties in reasoning and problem solving[247]; memory impairment[240,248-250]; problems with executive functioning and processing speed[248]; and cognitive impairment.[240,247,248] Reduced memory function is associated with older age, longer interval since HCT, chronic graft-versus-host disease, and long-term cyclosporine use.[251] Other predictors include fatigue and poor physical functioning. Lower education level and poorer social functioning appear to impact cognitive performance.[248] It is therefore prudent to query post-HCT patients regarding perceived deficits in neuropsychologic functioning and to refer patients with these problems to a neuropsychologist who is experienced in the follow-up care of HCT patients.

persistently elevated alanine aminotransferase (ALT) levels. Hepatitis C is the most prevalent type of hepatitis seen in survivors transfused before universal screening of the blood supply for this infection (implemented in the United States in July 1992). Cirrhosis and hepatocellular carcinoma are potential sequelae of untreated chronic viral hepatitis and potential causes of morbidity and mortality in this population. In a cohort of 431 pediatric patients in Italy who were diagnosed with leukemia or lymphoma before 1990 and completed treatment before August 1994, 17.2% (74 of 431) were anti–hepatitis C virus (HCV) positive.[175] Hepatocellular carcinoma or progression to liver failure was not seen in this group of patients after a 14-year median follow-up; however, due to the natural history of this disease, a longer follow-up is required to clearly define the risk for chronic HCV infection in this population. In a study of 3721 survivors of HCT,[176] the cumulative incidence of cirrhosis was estimated at 0.6% after 10 years and 3.8% after 20 years. The major risk factor for development of cirrhosis in this cohort was chronic hepatitis C infection, evident in 81% (25 of 31) of patients with cirrhosis. These Seattle investigators estimate that approximately 30% to 35% of their patients transplanted before 1991 were infected with hepatitis C and are at risk for the development of cirrhosis and related complications. In addition, iron overload associated with HCT for hematopoietic malignancies may also be a contributing factor to hepatotoxicity in survivors.[177,178]

Second and Subsequent Malignancies

Second or subsequent malignancies are defined as histologically distinct cancers developing after the occurrence of a first cancer. Second malignant neoplasms are one of the most devastating consequences of cancer therapy. Subsequent malignancies are conventionally categorized into two major types: therapy-related myelodysplastic syndrome and acute myeloid leukemia (t-MDS/AML) or solid tumors. The latency between diagnosis and treatment of the primary cancer and the development of t-MDS/AML is generally short, whereas nonhematopoietic malignancies or solid tumors seem to have a longer latency, and the risk continues to rise for 3 or more decades. The second malignancy experience differs across the age spectrum, in terms of the types of second malignancies observed, magnitude of risk, latency, and the mediating and moderating factors. This is due to the difference in susceptibility of individual tissues at different ages to the genotoxic insult and the presence of lifestyle factors that can modify the risk. A wide variety of factors influence the risk for second malignancies.

Several large epidemiologic studies have attempted to determine the magnitude of the burden of second cancers after adult-onset primary cancer. For example, 470,000 cancer patients registered between 1953 and 1991 in Finland were followed for the development of a second cancer.[179] Overall, the cohort was not at an increased risk for developing a second cancer when compared with the risk for cancer in an age- and sex-matched healthy population. However, patients less than 50 years of age at the diagnosis of their primary cancer were at a 1.7-fold increased risk for developing a second cancer. Another cohort of 633,964 cancer patients diagnosed between 1958 and 1996 in Sweden and followed for the development of subsequent cancers revealed a modestly increased risk (less than twofold), when compared with the general population.[180] A third cohort of 250,000 patients followed for the development of a second cancer in the United States revealed that cancer patients had a 1.3-fold increased risk for developing a second cancer, when compared with the general population.[181] However, when we look at second cancers after cancers in childhood or adolescence, a clearer and somewhat different picture emerges.

Studies following large cohorts of childhood cancer survivors have reported a threefold to sixfold increased risk for a second cancer compared with the background incidence of cancer in the general population, and this risk continues to increase as the cohort ages. Follow-up of a Nordic cohort of 30,880 patients diagnosed with their first cancer at 21 years of age or younger between 1943 and 1987 resulted in the identification of 247 second cancers.[182] The estimated cumulative incidence of second cancers in this cohort was 3.5% at 25 years, and the cohort was at a 3.6-fold increased risk for developing a second cancer when compared with an age- and sex-matched healthy population. A retrospective cohort of 14,359 children diagnosed with common cancers in the United States before the age of 21 years between 1970 and 1986, and surviving at least 5 years, was followed for the development of second cancers by the Childhood Cancer Survivor Study.[183] The estimated 30-year cumulative incidence was 7.9% for second cancer excluding nonmelanoma skin cancers. Overall, the cohort was at a sixfold increased risk for developing a second cancer. The relative risk for developing a second malignancy was significantly increased for survivors of HL (standardized incidence ratio [SIR] = 8.7). However, only 2.6 excess malignancies occurred per 1000 years of patient follow-up; therefore, even though the incidence of a second cancer is greater in those whose first cancer occurred in early life, the annual excess risk for second cancers in this group is still very small. Female sex, older age at diagnosis, earlier treatment era, HL, and treatment with radiation were identified to increase the risk for subsequent malignancies. Finally, childhood cancer survivors are at risk for the development of multiple primary malignancies. Armstrong et al[184] examined the occurrence of multiple subsequent neoplasms in long-term survivors of childhood cancer and reported the cumulative incidence of a third primary malignancy to be 46.9% at 20 years after the second primary malignancy.

The magnitude of risk for subsequent malignant neoplasms after HCT performed in childhood or in adults ranges from fourfold to 11-fold that of the general population. Several host and clinical factors are associated with an increased risk for subsequent malignant neoplasms after HCT. These include age at HCT, pre-HCT exposure to chemotherapy and radiation, exposure to TBI as part of conditioning, infection with oncogenic viruses (Epstein-Barr virus [EBV] and hepatitis B and C viruses [HBV and HCV]), prolonged immunosuppression after HCT, autologous versus allogeneic HCT, and original cancer.[185,186] t-MDS/AML is now the major cause of nonrelapse mortality in patients undergoing autologous HCT for patients with a primary diagnosis of HL or NHL.[187,188] The cumulative probability of t-MDS/AML ranges from 1.1% at 20 months to 24.3% at 43 months after autologous HCT, with a median latency of 12 to 24 months after HCT (range, 4 months to 6 years). Using the World Health Organization classification, two types of t-MDS/AML are recognized, related closely to the therapeutic exposure: alkylating agent/radiation and topoisomerase II inhibitor.[189] The alkylating agent–related t-MDS/AML typically develops 4 to 7 years after exposure. Cytopenias are common. Roughly 65% of the patients present with myelodysplasia; the remaining present with AML but carry myelodysplastic features. Abnormalities involving chromosomes 5 (-5/del[5q]) and 7 (-7/del[7q]) are frequently seen. AML secondary to topoisomerase II inhibitors presents as overt leukemia, without a preceding myelodysplastic phase. The latency is brief, ranging from 6 months to 5 years, and is associated with balanced translocations involving chromosome bands 11q23 or 21q22. The magnitude of risk for solid tumors exceeds twofold that of an age- and sex-matched general population.[190-192] Rizzo et al[191] report the risk for solid tumors in a multiinstitutional cohort of 28,874 allogeneic HCT recipients. Although the overall risk for solid malignancies is twofold that of the general population, the risk reaches threefold among patients followed for 15 or more years after HSCT.[191] Solid timors are unequivocally related to radiation therapy used to treat the primary cancer, they typically have a long latency, and the risk is high among those exposed to irradiation at a young age. Rizzo et al demonstrate that the risk for developing a non–squamous cell carcinoma (SCC) following conditioning radiation is dependent on age at exposure to radiation. Thus, among patients exposed to radiation at age less than 30 years, the risk is ninefold that of the general population, whereas for those older than 30 years, it approaches that of the general population.

Evaluations of large cohorts of patients with childhood ALL entered on Children's Oncology Group therapeutic trials have shown

that the cumulative incidence of second and subsequent malignancies approaches 2% at 15 years from diagnosis of ALL.[193,194] CNS tumors, the most common second malignancy observed among survivors of childhood ALL, are predominantly associated with exposure to cranial irradiation.[195] Histologically, radiation-related late-occurring neoplasms include high-grade gliomas, (glioblastomas and malignant astrocytomas), peripheral neuroectodermal tumors, ependymomas and meningiomas, and basal cell carcinomas (BCCs).[193,194,196,197] Other commonly reported second cancers within the population of ALL survivors include thyroid cancer, lymphoma, and t-MDS/AML. Secondary thyroid malignancies, typically papillary carcinoma, are generally associated with radiation exposure to the thyroid gland as part of CNS irradiation, either prophylactic or for treatment of CNS leukemia. Thyroid malignancy has been reported to represent between 6% and 17% of secondary cancers among large cohorts of ALL survivors[193-195] and typically develops 10 or more years from treatment. As is true of de novo thyroid malignancy, the long-term outcome for survivors diagnosed with a secondary thyroid malignancy is excellent. The risk for t-MDS/AML after therapy for ALL is generally low, except among those patients treated with epipodophyllotoxin therapy, where a cumulative risk of 3.8% at 6 years has been reported.[198] t-AML associated with topoisomerase II inhibitors is characterized typically by a shorter latency period (3 to 5 years from therapeutic exposure) than that seen for t-MDS/AML after alkylating agents, lack of a myelodysplastic phase, and the presence of 11q23 rearrangements with mutations in the MLL gene. Epipodophyllotoxin-associated secondary AML depends more on the schedule of drug administration than total cumulative dose.[199]

Survivors of HL clearly represent one of the subgroups of cancer survivors who are at a very high risk for secondary cancer. This is particularly true for patients who received earlier regimens with predominantly radiation-based therapies, for which an approximate 10-fold increased risk has been reported.[195] A number of studies, with cohorts ranging from 499 to 5925 HL patients, have reported cumulative incidence of second malignancies to range from 7.6% at 20 years to 18.0% at 30 years.[195,200-203] Early studies of HL identified the increased risk for t-MDS/AML among patients treated with MOPP-based therapy, which included mechlorethamine and cyclophosphamide.[204,205] These alkylating agent–associated t-MDS/AMLs are characterized by a relatively short latency period, presence of chromosomal abnormalities involving chromosomes 5 and/or 7, and are often preceded by a phase of myelodysplasia.[206] The risk for t-MDS/AML usually does not extend beyond the first 10 to 15 years after therapeutic exposure. Extended follow-up studies of early cohorts have already reported excess risks for lung and gastrointestinal cancers.[207-211] More recent studies, with longer follow-up of cohorts, demonstrate that the most frequently observed solid second malignancies include breast cancer, thyroid cancer, and bone/soft tissue sarcomas.[207,212,213] With extended follow-up of cohorts of young HL survivors, increased risks for common adult carcinomas, including colorectal, lung, and stomach have emerged, and these cancers are being diagnosed at younger ages than observed in the general population.[207] In a large population-based study of solid tumor risk among 18,862 5-year survivors reported to 13 registries, breast, lung, and gastrointestinal cancers accounted for almost two-thirds of the estimated excess number of cases.[214]

Breast Cancer

Breast cancer is the most commonly reported second malignancy among female survivors of childhood Hodgkin lymphoma treated with mantle field irradiation, and the risk remains markedly elevated for many decades after exposure.[195,200-203] An update of the Late Effects Study Group cohort found female survivors to have a 55-fold increased risk for breast cancer compared with the general population, and the cumulative incidence of developing a secondary breast cancer approached 20% at 45 years of age.[207] Moreover, 40% of identified cases were found to have developed contralateral disease. Secondary thyroid cancer, the second most common solid tumor reported among survivors of childhood HL, is strongly associated with radiation therapy, occurs more frequently in females, and is associated with an approximate 36-fold increased risk over the general population. As the cohort of pediatric HL survivors continues to age, it is likely that an increasing number of other forms of malignancy associated with an excess risk will emerge. Using the resources offered by the Childhood Cancer Survivor Study, Inskip et al[215] sought the relation between radiation dose and breast cancer in childhood cancer survivors. The risk for breast cancer increased in a linear fashion with radiation dose, and it reached 11-fold for local breast doses of approximately 40 Gy relative to no radiation. Risk associated with breast irradiation was sharply reduced among women who received 5 Gy or more to the ovaries. Although the risk for breast cancer is elevated among women who received therapy at a young age, the risk declines with age at radiation, such that the relative risks compared with the general population are comparable to those of the general population after age 35. Travis et al[216] developed estimates of cumulative absolute risk for use in counseling patients. For example, the cumulative absolute risks for an HL survivor who was treated at age 25 years with a chest radiation dose of 40 Gy or more without alkylating agents were estimated to be 1.4% after 10 years, 11% after 20 years, and 29% after 30 years.[216] There appears to be a protective effect of early menopause either because of alkylating agents or radiation dose above 5 Gy to the ovaries, suggesting that ovarian hormones play an important role in promoting tumorigenesis once an initiating event has been produced by radiation.[217,218] The 25-year cumulative incidence of breast cancer is reported to be 11% after allogeneic HCT.[219] Allogeneic HCT survivors are at a 2.2-fold increased risk for developing breast cancer, when compared with age- and sex-matched general population. The median latency from HCT to diagnosis of breast cancer is 12.5 years. The incidence is higher among those exposed to TBI (17%) than among those who did not receive TBI (3%). The risk is increased among those exposed to TBI at a younger age.

Thyroid Cancer

Bhatti et al[220] quantified the long-term risk for thyroid cancer associated with radiation treatment among 12,547 5-year survivors of childhood cancer from the Childhood Cancer Survivor Study Cohort. Thyroid cancer risk increased linearly with radiation dose up to 20 Gy, where the relative risk peaked at 14.6-fold. At thyroid radiation doses above 20 Gy, a downturn in the dose-response relationship was observed. Sex, age at exposure, and time since exposure were identified to be significant modifiers of the radiation-related risk for thyroid cancer. HCT recipients are at a 3.3-fold increased risk for thyroid cancer, when compared with age- and sex-matched general population.[221] Age younger than 10 years at HCT, neck radiation, female sex, and chronic GVHD are associated with an increased risk for thyroid cancer. Thyroid cancer develops after a latency of 8.5 years and is associated with an excellent outcome.

Central Nervous System Tumors

Radiation is the most important risk factor for the development of a new CNS tumor. Neglia et al[222] described the dose-response relationship between radiation exposure and development of new primary neoplasms of the CNS. They also described the excess risk over time and the modifying effect of other host and treatment factors. A total of 116 subsequent CNS tumors were included in the analysis.[222] Gliomas occurred a median of 9 years from the original diagnosis; for meningiomas, the latency was 17 years. Radiation exposure was associated with increased risk for subsequent glioma (OR, 6.78) and meningiomas (OR, 9.94). The dose-response relationship for the excess relative risk was linear. For gliomas, the excess relative risk per gray was highest among children exposed at less than 5 years of age. The overall SIR was 8.7 for the gliomas, and the excess absolute risk (EAR) was 1.9 per 1000 person-years.

t-MDS/AML

Several studies have described an increased risk for t-MDS/AML with older age at HCT[185]; pretransplantation therapy with alkylating agents, topoisomerase II inhibitors, and radiation therapy[187]; use of peripheral blood hematopoietic cells; stem cell mobilization with etoposide; difficult stem cell harvests; conditioning with TBI; number of $CD34^+$ cells infused; and a history of multiple transplants.[185,187] Thus t-MDS/AML after autologous HCT is the result of cumulative toxicity that includes pre-HCT chemotherapy (alkylators and topoisomerase II inhibitors), topoisomerase II inhibitors used for stem cell mobilization, and transplantation-related conditioning. The diagnosis of t-MDS/AML after autologous HCT confers a uniformly poor prognosis, with a median survival of 6 months in patients treated with conventional chemotherapy.

Skin Cancer

Among allogeneic HCT recipients, the incidence of BCC is 6.5% at 20 years, whereas that for SCC is 3.4%.[223] TBI increases the risk for BCC especially in younger patients. SCC risk is increased among patients with acute GVHD, whereas chronic GVHD is associated with both BCC and SCC.[224] Immunologic alterations predispose patients to SCC of the buccal cavity particularly, hence the association with chronic GVHD.[223] In patients with prolonged immunosuppression, oncogenic viruses such as human papillomavirus contribute to SCC of the skin and buccal mucosa.[223] Solid tumors commonly seen after HCT include melanoma, cancers of the oral cavity and salivary glands, brain, liver, cervix, thyroid, breast, bone, and connective tissues.[190,191]

The COG LTFU guidelines recommend monitoring for t-MDS/AML with annual complete blood cell count for 10 years after exposure to alkylating agents or topoisomerase II inhibitors.[62] Most other subsequent malignancies are associated with radiation exposure. Screening recommendations include careful annual physical examination of the skin and underlying tissues in the radiation field. Mammography, the most widely accepted screening tool for breast cancer in the general population, may not be the ideal screening tool by itself for radiation-related breast cancers occurring in relatively young women with dense breasts, hence the American Cancer Society recommends including adjunct screening with magnetic resonance imaging (MRI). Thus the following are recommendations for females who received radiation with potential impact to the breast (i.e., radiation doses of 20 Gy or higher to the mantle, mediastinal, whole lung, and axillary fields): monthly breast self-examination beginning at puberty; annual clinical breast examinations beginning at puberty until age 25 years; and a clinical breast examination every 6 months, with annual mammograms and MRI scans beginning 8 years after radiation or at age 25 (whichever occurs later). Screening of those at risk for early-onset colorectal cancer (i.e., radiation doses of 30 Gy or higher to the abdomen, pelvis, or spine) should include colonoscopy every 5 years beginning at age 35 years or 10 years following radiation (whichever occurs last).[62] Joint recommendations for monitoring long-term survivors of HCT by the EBMT/CIBMTR/ASBMT suggest that all recipients of HCT should be advised of risks for subsequent malignancies and encouraged to perform screening self-examinations, such as breast and skin examinations. All patients should be advised to avoid high-risk behaviors, including avoidance of tobacco or excessive unprotected exposure of skin to ultraviolet light.[63]

Late Mortality

Late recurring disease, as well as sequelae of the treatment for hematologic malignancies, can have a direct or indirect impact on overall mortality. Several large studies of late mortality among 5-year survivors of childhood cancer have been conducted.[225-227] In a study of the 5-year survivors in the United States,[227] the probability of survival 30 years from diagnosis was 82%. When compared with the U.S. population, the absolute excess risk for death from any cause was 7.36 deaths per 1000 person-years, and the cohort was at an 8.4-fold increased risk for premature death. Increase in cause-specific mortality was seen for deaths due to subsequent malignancies (standardized mortality ratio [SMR], 15.2), cardiac (SMR, 7.0), pulmonary (SMR, 8.8), and other medical conditions (SMR, 2.6). At 25 years from diagnosis, the death rate due to a subsequent malignancy exceeded that due to all other causes.

Late mortality due to recurrent disease and complications of therapy has also been described among patients who underwent HCT for hematologic malignancies.[188,228] Socie et al[228] reported that among 6691 individuals who underwent allogeneic transplant for hematologic malignancies and were free of disease 2 years after transplantation, the probability of living for 5 more years was 89%. The authors concluded that the disease is probably cured in patients who receive an allogeneic HCT as treatment for AML, ALL, chronic myeloid leukemia (CML), or aplastic anemia and who remain free of their original disease 2 years later. However, for many years after transplantation, the mortality rate among these patients is higher than that in a normal population. Wingard et al[229] described the long-term survival and late deaths after allogeneic HCT, updating the previous study from CIBMTR. The conditional survival at 10 years after HCT was 85%. The chief risk factors for late death were older age and chronic GVHD.[229] Bhatia et al[188] assessed late mortality in 854 survivors who underwent autologous HCT for hematologic malignancies and survived 2 or more years following transplant. After a median follow-up of 7.6 years, the overall survival was 68.8% ± 1.8% at 10 years, and the cohort was found to be at a 13-fold increased risk for late death when compared with the general population. Relapse of primary disease (56%) and subsequent malignancies (25%) were leading causes of late death. On the other hand, among 1479 allogeneic HCT recipients who had survived 2 or more years, the conditional survival probability approached 80%, and the cohort was at a 9.9-fold increased risk for late death, when compared with the general population. Relative mortality decreased with time but remained significantly elevated at 15 years after HCT. Relapse of primary disease and chronic GVHD were the leading causes of premature death.[40] In a recent study, Martin et al[230] described the life expectancy in patients surviving more than 5 years after HCT. Estimated survival of the cohort at 20 years after HCT was 80.4%. Mortality rates remained fourfold to ninefold higher than the expected population rate for at least 30 years after transplantation, yielding an estimated 30% lower life expectancy compared with that in the general population. The leading causes of excess deaths were subsequent malignancies and recurrent disease.

Psychosocial Effects

Survivors of hematopoietic malignancies are at risk for adverse psychosocial outcomes that may affect the overall quality of life, including anxiety, depression, posttraumatic stress disorder, and barriers to accessing the health care system due to problems obtaining health insurance coverage. The impact of cancer therapy on psychosocial functioning is dependent on many variables, including intensity and duration of therapy, treatment-related complications, family functioning, developmental processes, and treatment-specific sequelae such as altered cognitive or physical functioning.[231] An increased risk for adverse socioeconomic outcomes has been associated with younger age and cranial radiation therapy in survivors of childhood acute ALL.[232]

Results from an analysis of 5736 long-term survivors of childhood leukemia and lymphoma demonstrated that although a relatively low proportion reported symptoms indicative of depression (4.6%) and somatic distress (10.8%), they were significantly more likely to report these symptoms when compared with sibling controls.[233] In a study of 6542 childhood cancer survivors (55% of whom were survivors of leukemia/lymphoma), the risk for posttraumatic stress disorder was increased by 4.6-fold, 4.1-fold, and 3.8-fold for survivors of HL, NHL, and leukemia, respectively, compared with sibling controls;

Evaluating Survivors for Potential Late Effects

To diminish the incidence and severity of untoward late effects and to improve the quality of survival for patients with hematopoietic malignancies, systematic evaluation of outcomes with subsequent modification of current and future therapies is required. To decrease late morbidity and mortality rates and to meet the specialized health care needs of this group of patients, ongoing comprehensive follow-up care with attention to early detection and intervention for late effects are essential.

Patients are generally eligible to enter formal long-term follow-up care when the risk for relapse of their primary disease is minimal. For most hematologic malignancies, this occurs when a patient is at least 2 years off therapy. When a patient enters long-term follow-up, the focus of care shifts from vigilant surveillance for disease recurrence to a survivorship model of health maintenance or promotion and management of treatment-related late effects. Effective management of these late effects requires ongoing surveillance, early intervention, and when possible, prevention.

The long-term complications of treatment for which an individual survivor is at risk are determined by several factors, including the patient's diagnosis, age at treatment, specific chemotherapeutic agents received (including cumulative doses), specific radiation fields and doses, therapy-related complications, degree of psychosocial support received, genetic predisposition, and current health-related behaviors (e.g., diet, physical activity, tobacco, and alcohol use).

increased risk was associated with lower educational level (high school or less), lower income (<$20,000 annually), being unmarried, being unemployed, and having had more intensive treatment.[234] Long-term survivors of adult-onset HL report poorer health-related quality of life, primarily in physical health, when compared with a healthy general population.[235] Survivors of HL also appear to be at increased risk for psychosocial distress when compared with acute leukemia survivors; areas of greatest impact for these patients include impaired family and sexual functioning.[236] There is growing interest in the reported occurrences of fatigue and sleep disturbances among cancer survivors, particularly those with HL,[6,237,238] which may contribute to depression.

Fatigue, psychologic distress, psychiatric symptoms, mood disturbances, and sexual difficulties are commonly reported by HCT survivors.[239] Risk factors for impaired health-related quality of life include older age, advanced disease at transplantation, presence of chronic GVHD, and lower level of education. Fatigue and sleep disturbances have been reported in up to 65% of the patient cohorts studied,[240] and sexual disturbances are prevalent in 25% of HCT survivors[241] (see box on Evaluating Survivors for Potential Late Effects).

POTENTIAL LATE EFFECTS BY DIAGNOSIS

Therapeutic approaches to hematologic malignancies vary widely depending on the patient's age at diagnosis, biologic subtype and staging of disease, year (era) of diagnosis, initial response to therapy, and physician/institutional preference. Even though two patients may share an identical diagnosis, their risks for late effects may differ significantly because of differences in therapy, age at exposure to therapy, or pharmacogenetics. General associations of late effects with conventional treatment for common hematologic malignancies are reviewed in Tables 94-1 to 94-3. The risk for specific late effects in survivors who have undergone HCT depends on the conditioning regimen, donor source, complications experienced during the transplantation process, presence or absence of GVHD, and prior cancer therapy. Transplantation-related sequelae have been reviewed throughout the text of this chapter.

Table 94-1 Late Effects Associated With Conventional Therapy for Acute Lymphoblastic Leukemia and Non-Hodgkin Lymphoma

Common Therapeutic Exposures	Potential Late Effects
Vincristine	Peripheral neuropathy, Raynaud phenomenon
Corticosteroids	Cataracts, osteopenia, osteoporosis, avascular necrosis
Asparaginase	No known late effects
Mercaptopurine	Hepatic dysfunction (rare)
Thioguanine	Portal hypertension, hepatotoxicity (when used continuously in maintenance therapy)
Methotrexate (systemic)	Osteopenia, osteoporosis, osteonecrosis, renal dysfunction (rare), hepatic dysfunction (rare)
Methotrexate (intrathecal, high-dose), or cytarabine (high-dose)	Neurocognitive deficits, clinical leukoencephalopathy
Cranial or craniospinal irradiation	Neurocognitive deficits, clinical leukoencephalopathy, cataracts, hypothyroidism, second malignant neoplasm in radiation field (e.g., skin, thyroid, brain), short stature, scoliosis or kyphosis, obesity
Anthracyclines	Cardiomyopathy, arrhythmias, subclinical left ventricular dysfunction, secondary AML
Cyclophosphamide	Hypogonadism, hemorrhagic cystitis, dysfunctional voiding, bladder malignancy, secondary AML or MDS
Blood products	Chronic viral hepatitis, HIV

AML, Acute myeloid leukemia; *HIV,* human immunodeficiency virus; *MDS,* myelodysplastic syndrome.

Table 94-2 Late Effects Associated With Conventional Therapy for Acute Myeloid Leukemia

Common Therapeutic Exposures	Potential Late Effects
Anthracyclines	Cardiomyopathy, arrhythmias, subclinical left ventricular dysfunction, secondary acute myeloid leukemia
Corticosteroids	Cataracts, osteopenia, osteoporosis, avascular necrosis
Asparaginase	No known late effects
Cytarabine (high dose)	Neurocognitive deficits, clinical leukoencephalopathy
Blood products	Chronic viral hepatitis, human immunodeficiency virus infection

Acute Lymphoblastic Leukemia

ALL is a heterogeneous disease. Therapy for ALL ranges from a relatively innocuous, antimetabolite-based approach for low-risk childhood ALL[242] to marrow-ablative therapy followed by HCT for very high-risk disease in all age-groups.[243,244] The risk for long-term complications for individual survivors varies widely and is dependent on

Table 94-3 Late Effects Associated With Conventional Therapy for Hodgkin Lymphoma

Common Therapeutic Exposures	Potential Late Effects
Anthracyclines	Cardiomyopathy, arrhythmias, subclinical left ventricular dysfunction, secondary AML or MDS
Corticosteroids	Cataracts, osteopenia, osteoporosis, avascular necrosis
Bleomycin	Pulmonary dysfunction
Vincristine, vinblastine	Peripheral neuropathy, Raynaud phenomenon
Procarbazine, mechlorethamine, dacarbazine	Hypogonadism, infertility, secondary AML or MDS
Cyclophosphamide	Hypogonadism, infertility, hemorrhagic cystitis, dysfunctional voiding, bladder malignancy, secondary AML or MDS
Mantle irradiation	Hypothyroidism, premature cardiovascular disease, cardiac valvular disease, cardiomyopathy, arrhythmias, carotid artery disease, scoliosis or kyphosis, second malignant neoplasm in radiation field (e.g., thyroid, breast), pulmonary dysfunction
Inverted Y irradiation	Hypogonadism, infertility, adverse pregnancy outcome, second malignant neoplasm in radiation field (e.g., gastrointestinal)
Splenectomy	Acute life-threatening infections
Blood products	Chronic viral hepatitis, HIV

AML, Acute myeloid leukemia; *HIV,* human immunodeficiency virus; *MDS,* myelodysplastic syndrome.

the specific therapy received as well as the patient's age at time of treatment. Potential late effects that may occur as a consequence of conventional therapy for ALL are listed in Table 94-1.

Acute Myeloid Leukemia

Therapy for AML is generally more intense and of shorter duration than that used for treatment of ALL. Higher doses of anthracycline chemotherapy are often employed, as is consolidation therapy with HCT. Typically patients with AML receive less CNS-directed therapy than those with ALL. Examples of potential late effects associated with conventional therapy for AML are listed in Table 94-2.

Hodgkin Lymphoma

Therapy for HL relies on the use of alkylating agents, antitumor antibiotics (including anthracyclines and bleomycin), corticosteroids, and radiation therapy. Some patients may be apslenic as a consequence of the staging procedures performed in the earlier era. Examples of potential late effects associated with conventional therapy for HL are listed in Table 94-3.

Non-Hodgkin Lymphoma

The potential late effects after therapy for NHL are therapy specific and similar to those experienced by survivors of ALL (see Table 94-1). Those patients whose treatment included HCT are, of course, also at risk for transplantation-related sequelae.

Late Effects Research: What Is Needed

Medical Issues Faced by This Population
Premature death
Second malignancies
Organ dysfunction (e.g., cardiac, pulmonary, gonadal)
Impaired growth and development
Decreased fertility
Neurocognitive impairment
Difficulties obtaining employment and insurance
Overall reduced quality of life

Issues to Be Considered by Physicians Providing Care to This Population
Providing long-term follow-up care for cancer survivors
Models of care delivery
- Pediatric oncology-based
- Adult oncology-based
- Community medicine–based

Guidelines for ongoing screening and management
- Screening for potential complications
- Health protective counseling or interventions
- Management of identified complications

Major Clinical and Research Challenges
Cancer survivorship research continually changing because of new:
- Therapeutic agents or combinations of agents
- Radiation oncology techniques
- Surgical procedures
- Supportive care techniques

Future Directions
Much of the available information relates to outcomes within the first decade after treatment, and only minimal data address the longer-term outcomes that may occur later.

Research is needed to more clearly define the survivors at greatest risk for specific outcomes.

Research is needed to identify genetic predispositions to certain key outcomes and the roles of gene-environment interactions.

Research is needed to identify the role of lifestyle choices (e.g., alcohol, tobacco, diet, exercise) in terms of modification of the risks for these late outcomes.

Research is needed to understand the potential long-term impact of cancer therapy to effectively counsel survivors and offer effective intervention strategies to prevent or minimize the impact of adverse late effects.

Interventions are needed to include scientifically valid, evidence-based recommendations for clinical follow-up of survivors, which should include screening for potential late effects and application of proven approaches for health promotion.

Chronic Myeloid Leukemia

Long-term survivors of CML have usually either undergone HCT or are receiving tyrosine kinase inhibitors long-term. Among HCT recipients, there is a significant risk for late effects as a result of the transplantation conditioning regimen, as well as treatment for and sequelae of GVHD.[17] With the transition over the past decade to tyrosine kinase inhibitor therapy for CML as the predominant treatment modality, the long-term effects of these agents will need to be studied in detail in the growing cohort of CML survivors[245] (see box on Late Effects Research: What Is Needed and the section Providing Clinical Care to Survivors).

PROVIDING CLINICAL CARE TO SURVIVORS

A comprehensive treatment summary should be prepared for each patient entering long-term follow-up (Table 94-4) and a copy given to each survivor with instructions to share this information with all health care providers. Survivors should undergo annual comprehensive, multidisciplinary health evaluations (Fig. 94-1) with special attention to the detection of potential late effects specific to the patient's diagnosis and treatment history (Table 94-5). Guidelines for long-term follow-up of survivors of hematologic malignancies and those who underwent hematopoietic cell transplantation in childhood, adolescence, or young adulthood have been developed by the Children's Oncology Group[62] and are available at http://www.survivorshipguidelines.org. Because certain late effects have prolonged asymptomatic intervals before becoming clinically evident (e.g., late-onset congestive heart failure as a result of anthracycline-induced cardiomyopathy), ongoing evaluation is important to identify and provide early intervention for these potential complications. Health education regarding potential health risks and risk-reduction measures should be provided to each survivor. Targeted health education materials related to potential late complications of therapy during childhood, adolescence, or young adulthood have been developed by the Children's Oncology Group[246] and are available at http://www.survivorshipguidelines.org. After completion of each annual evaluation, identified late effects should be systematically recorded, and recommendations for any additional testing and for health maintenance and promotion should be shared with the patient and his or her primary health care provider. To optimize future follow-up care for all survivors, patients should be invited to participate in any relevant research studies for which they are eligible (see box on Late Effects Research: What Is Needed).

FUTURE DIRECTIONS

As treatment for hematopoietic malignancies continues to improve, follow-up care for survivors of these diseases must be provided in a comprehensive manner. To minimize treatment-related sequelae and provide early intervention for identified late effects, the risks of long-term complications for each individual survivor must be evaluated;

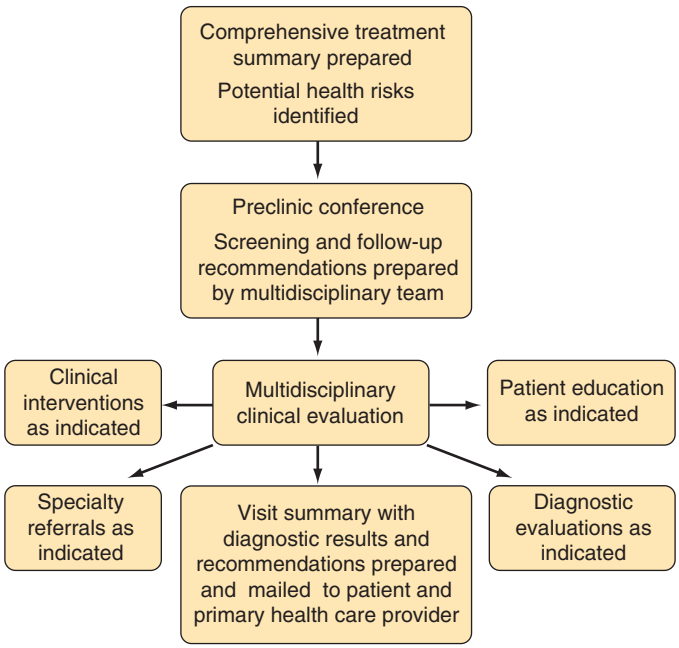

Figure 94-1 ANNUAL COMPREHENSIVE MULTIDISCIPLINARY HEALTH EVALUATION FOR THE CANCER SURVIVOR.

Table 94-4 Comprehensive Treatment Summary

Topic	Specific Information to Include
Demographics	Name Record number or patient identification number Date of birth Sex Race or ethnicity
Diagnosis	Date or age at diagnosis Referring physician or institution Treating physician or institution Presenting symptoms Past medical history Family history (including cancer in first- or second-degree relatives) Physical examination findings at presentation Initial diagnostics (complete blood cell count, chemistry panel, radiographic studies) Diagnostic procedures (biopsies, cytologic studies) Pathology (morphology, histology, cytochemistry, flow cytometry) Cytogenetics Central nervous system status (if applicable) Stage (if applicable) Metastatic sites (if applicable) Initial response to therapy (e.g., rapid early response [RER], slow early response [SER], date first complete remission achieved) Relapse(s) dates, age at relapse(s), relapse site(s)
Treatment	Date of initial treatment (initiated and completed) Date(s) for treatment of relapse (initiated and completed) Final off-therapy date Chemotherapy agents received, including route of administration (list all) Cumulative doses (in mg/m^2) and age at treatment for all alkylators, anthracyclines, and heavy metals Dose ranges for cytarabine and methotrexate (e.g., standard dose versus high dose >1000 mg/m^2) Radiation fields, doses, shielding, age at treatment Surgical procedure(s) Transfusion(s), including all blood or serum products Stem cell transplantation(s), including donor source, preparative regimen, GVHD prophylaxis or treatment
Acute complications	Significant therapy-related complications (e.g., tumor lysis, septic shock, typhlitis, acute GVHD) Significant treatment required for complications (e.g., hemodialysis, amphotericin, aminoglycosides)
Complications after therapy	Significant complications after completion of therapy (e.g., herpes zoster, acute life-threatening infection after splenectomy)

Modified from Children's Oncology Group Summary of Cancer Treatment, 2008. http://www.survivorshipguidelines.org.
GVHD, Graft-versus-host disease.

Table 94-5 Monitoring for Potential Late Effects

Potential Late Effects	Therapeutic Exposure	Recommended Monitoring	Suggested Interventions
Adverse psychosocial effects (e.g., depression, anxiety, posttraumatic stress disorder, limitations in health care access, risky behaviors, psychosocial disability due to pain, fatigue)	Diagnosis and treatment for hematologic malignancy	Clinical interview: yearly	Psychologic or social work consultation if indicated
Dental abnormalities (abnormal tooth development, increased susceptibility to caries and gum disease)	Chemotherapy Cranial irradiation TBI	Dental examination: every 6 months	Professional dental cleaning every 6 months; use of fluoridated toothpaste; topical fluoride applications as indicated; Panorex radiograph before orthodontic or dental procedures for patients treated before completion of tooth development
Peripheral neuropathy Raynaud phenomenon	Vincristine Vinblastine	Neurologic examination if symptomatic	Physical therapy if indicated; advise patient to protect against precipitating factors (e.g., cold environment)
Neurocognitive deficits	Methotrexate (intrathecal, high-dose systemic) Cytarabine (high-dose systemic) Cranial irradiation TBI	Formal neuropsychologic testing: baseline on entry to long-term follow-up; repeat as clinically indicated if evidence of impaired performance Clinical interview yearly, including assessment of educational and vocational progress	Referral for specialized educational services, curricular modifications, or vocational training programs if indicated
Clinical leukoencephalopathy	Methotrexate (intrathecal, high-dose systemic) Cytarabine (high-dose systemic) Cranial irradiation	Clinical evaluation: yearly brain MRI or CT if clinically indicated	Neurology consultation if clinically indicated
Cataracts	Corticosteroids Busulfan Cranial irradiation TBI	Funduscopic examination and visual acuity evaluation: yearly Ophthalmologic examination: yearly for patients who received TBI or cranial radiation ≥30 Gy; every 3 years for cranial radiation <30 Gy	Ophthalmology consultation if abnormalities detected
Xerophthalmia	Chronic GVHD related to HCT	History and eye examination yearly	Artificial tears, ophthalmology consultation if indicated
Xerostomia	Cranial irradiation Chronic GVHD related to HCT	Dental evaluation: every 6 months	Meticulous oral hygiene Artificial saliva products if indicated
Hearing loss	Platinum chemotherapy Aminoglycoside antibiotics Cranial irradiation	History and physical examination: yearly Audiogram: baseline at entry into long-term follow-up, then as clinically indicated; every 5 years for cranial radiation dose ≥30 Gy	Audiology consultation if indicated
Hypothyroidism Thyroid nodules Thyroid malignancy	Cranial, cervical, spinal, mantle, thoracic, or mediastinal irradiation; TBI	Free T_4, TSH, thyroid examination: yearly	Endocrine or surgical referral as indicated
Cardiomyopathy Arrhythmias Subclinical left ventricular dysfunction	Anthracyclines Chest or thoracic irradiation (e.g., mantle, mediastinal)	Detailed history of exertional tolerance (e.g., dyspnea on exertion, chest pain): yearly ECG (for evaluation of QT interval): baseline on entry into long-term follow-up; ECHO: baseline on entry into long-term follow-up, then every 1 to 5 yr as indicated based on age at therapy and total anthracycline or radiation dose	Cardiology consultation if indicated; additional cardiology evaluation of patients who are pregnant or planning to become pregnant if patient received ≥300 mg/m^2 of an anthracycline, radiation dose ≥30 Gy, or any dose of anthracycline combined with irradiation

Table 94-5 Monitoring for Potential Late Effects—cont'd

Potential Late Effects	Therapeutic Exposure	Recommended Monitoring	Suggested Interventions
Pericarditis Pericardial fibrosis Valvular disease Premature atherosclerotic heart disease	Chest or thoracic irradiation (e.g., mantle, mediastinal)	Consider cardiology consultation 5-10 yr after irradiation to evaluate risk for coronary artery disease in patients who received doses ≥40 Gy Fasting glucose and lipid profiles: every 2 yr	Cardiology consultation if indicated; additional cardiology evaluation in patients who are pregnant or planning to become pregnant if patient received anthracycline combined with radiation, ≥300 mg/m^2 anthracycline, or radiation dose ≥30 Gy
Pulmonary dysfunction (fibrosis, interstitial pneumonitis)	Bleomycin Busulfan Chest/thoracic irradiation TBI Chronic GVHD related to HCT	Pulmonary function testing and chest radiograph: baseline at entry into long-term follow up and as clinically indicated for patients with progressive dysfunction	Pulmonary consultation for symptomatic patients; influenza and pneumococcal vaccine; counsel patients to avoid smoking and avoid scuba diving
Thrombosis Vascular insufficiency Infection of retained cuff or line tract	Central venous catheter	History and physical examination: yearly as clinically indicated	Surgical referral as indicated
Hepatic dysfunction	Mercaptopurine, thioguanine, methotrexate (systemic) HCT	ALT, AST, bilirubin: baseline on entry into long-term follow-up; repeat if clinically indicated	If abnormal results for baseline studies, obtain prothrombin time (to assess hepatic synthetic function) and viral hepatitis screening
Chronic viral hepatitis	Blood products	Hepatitis C antibody and HCV-RNA by PCR: once if transfused before universal screening of blood supply (1992 in the United States) Hepatitis B surface antigen and core antibody: once if transfused before universal screening of blood supply (1972 in the United States)	Gastroenterology or hepatology consultation and annual AFP for patients with chronic hepatitis; hepatitis A and B immunizations in patients lacking immunity
HIV infection	Blood products	HIV-1 and HIV-2 antibodies: once if transfused before universal screening of blood supply (1985 in the United States)	Infectious disease consultation for patients with confirmed infection
Life-threatening infection	Splenectomy Splenic radiation ≥40 Gy Chronic active GVHD	Physical examination at time of febrile illness to evaluate degree of illness and for potential source of infection	Administer parenteral antibiotics and continue close medical observation in patients with temperature >38.3° C (101° F) or other signs of serious infection; immunize with pneumococcal, meningococcal, and HIB vaccines
Iron overload	HCT (and patients requiring multiple red blood cell transfusions)	Serum ferritin: at entry into long-term follow-up	If abnormal, consider chelation, or repeat as clinically indicated until within normal limits
Bowel obstruction Chronic enterocolitis Fistulas and strictures	Abdominal surgery Abdominal or pelvic irradiation Chronic GVHD related to HCT (esophageal strictures, vaginal stenosis)	History and physical examination: yearly and as clinically indicated Serum protein and albumin levels: yearly in patients with chronic diarrhea or fistula	Surgical and gastroenterology consultations as clinically indicated
Renal insufficiency	TBI Abdominal or splenic irradiation Ifosfamide Platinum chemotherapy Methotrexate	Blood pressure: yearly Urinalysis: yearly BUN, creatinine, electrolytes, calcium, magnesium, phosphorus baseline and repeat as clinically indicated	Nephrology consultation for proteinuria, hypertension, progressive renal insufficiency
Hemorrhagic cystitis Bladder fibrosis Dysfunctional voiding Bladder malignancy	Cyclophosphamide Ifosfamide Irradiation of abdomen, pelvis, iliac, inguinal sites	Urinalysis: yearly Voiding history: yearly	Urology consultation for incontinence, dysfunctional voiding, macroscopic hematuria (culture negative)

Continued

Table 94-5 Monitoring for Potential Late Effects—cont'd

Potential Late Effects	Therapeutic Exposure	Recommended Monitoring	Suggested Interventions
Growth hormone deficiency	Cranial irradiation TBI	Height, weight: every 6 months during puberty until growth is complete Obtain bone age in poorly growing children	Endocrine referral for patients failing to follow normal growth curve
Overweight/obesity	Cranial irradiation	BP, growth percentile, BMI: yearly	Endocrine referral as indicated
Metabolic syndrome	TBI	Fasting glucose, lipid profile and insulin level every 2 yr	
Hypogonadism Infertility	Alkylating agents Cranial irradiation Abdominal or pelvic irradiation Testicular irradiation Spinal irradiation >25 Gy TBI	Menstrual history, sexual function, height, weight: yearly Pubertal history, Tanner stage: yearly until maturity FSH, LH, estradiol, or testosterone: baseline at age 13 (females) or 14 (males) or at entry into long-term follow-up and for clinical symptoms of estrogen or testosterone deficiency Semen analysis: as indicated or requested by patient	Endocrine referral for hypogonadal patients (for hormone replacement therapy); reproductive endocrinology referral for patients desiring evaluation of fertility options
Precocious puberty	Cranial irradiation	Physical examination, height, weight, Tanner stage: yearly until maturity LH, FSH, estradiol, or testosterone: as clinically indicated in patients with accelerated pubertal progression Obtain bone age in rapidly growing prepubertal children	Endocrine referral as indicated
Adverse pregnancy outcomes (e.g., spontaneous abortion, premature delivery, low-birth-weight infant)	Irradiation of abdomen, pelvis, iliac, inguinal, para-aortic sites TBI	History: yearly and as clinically indicated	High-risk obstetric care
Osteopenia, osteoporosis	Corticosteroids Methotrexate (high-dose systemic) HCT	Bone-density study (DEXA scan or quantitative CT scan): baseline at entry into long-term follow-up, repeat as clinically indicated	Calcium and vitamin D supplementation; weight-bearing exercise; treatment of exacerbating conditions (e.g., hypogonadism); consider pharmacologic intervention (e.g., bisphosphonates)
Avascular necrosis	Corticosteroids Methotrexate (systemic) HCT	History: yearly; MRI if clinically indicated	Orthopedic consultation if indicated
Scoliosis/kyphosis	Irradiation of trunk (e.g., mantle, spine, abdomen, pelvis)	Physical examination of spine: yearly (every 6 months during pubertal growth spurt) Radiologic imaging of the spine if clinical evidence of scoliosis or kyphosis	Orthopedic referral
Joint contractures	Chronic GVHD related to HCT	Physical examination yearly	Orthopedic referral if indicated
Chronic infection	Chronic GVHD related to HCT	History: yearly	Prophylactic antiinfective agents; infectious disease consultation if indicated
Vitiligo Scleroderma Joint contractures Nail dysplasia Dysplastic nevi Skin cancer Secondary benign or malignant neoplasms in radiation field	Chronic GVHD related to HCT Irradiation (any field)	Physical examination: yearly Careful physical examination, inspection and palpation of irradiated skin and soft tissues: yearly	Dermatology or rehabilitation consultation if clinically indicated Dermatology or surgical referral and radiographs if indicated for any suspicious lesions

Table 94-5 Monitoring for Potential Late Effects—cont'd

Potential Late Effects	Therapeutic Exposure	Recommended Monitoring	Suggested Interventions
Bone malignancies Brain tumor	Cranial irradiation	History and physical examination: yearly Brain MRI: baseline at maturity for all patients and as clinically indicated	Neurosurgical consultation as indicated
Breast cancer	Chest or thorax irradiation ≥20 Gy (mantle radiation field)	Clinical breast examination: yearly until age 25, then every 6 months Mammogram and breast MRI: yearly beginning at age 25 or 8 yr after irradiation (whichever comes last)	Teach breast self-examination; instruct patient to perform monthly self-examination and report changes immediately; surgical consultation if clinically indicated
Gastrointestinal malignancy	Abdominal, pelvic, spinal irradiation ≥30 Gy	Colonoscopy every 5 years beginning 10 years after radiation or at age 35, whichever comes last; or more frequently as clinically indicated	Surgical consultation if indicated
AML (preceding myelodysplastic phase associated with alkylating agents)	Anthracyclines Epipodophyllotoxins Alkylating agents Stem cell priming with etoposide Autologous transplantation for NHL or Hodgkin lymphoma	Physical examination, CBC and differential: yearly for 10 yr after therapy Bone marrow evaluation if clinically indicated	Counsel patient to report fatigue, bruising, bleeding, bone pain

Modified from Children's Oncology Group: *Long-term follow-up guidelines for survivors of childhood, adolescent, and young adult cancers,* version 3.0, 2008, Children's Oncology Group. http://www.survivorshipguidelines.org.

however, it is important that these risks are kept in perspective. In reality, most survivors of hematologic malignancies have the potential to lead full lives with excellent performance status and minimal to no physical limitations. The overall goal of follow-up care is to assist each patient in maximizing his or her full potential for a healthy life while balancing the small, but real, risk for potential complications that may arise. Providing this type of ongoing comprehensive follow-up care is an essential service for survivors of hematologic malignancies.

CHAPTER 95

OVERVIEW AND HISTORICAL PERSPECTIVE OF CURRENT CELL-BASED THERAPIES

Leslie E. Silberstein and Helen E. Heslop

The discovery in 1900 by Karl Landsteiner of the ABO blood group system paved the way for transfusion therapy, that is, the ability to safely infuse living blood cells as a therapeutic modality (see Chapters 111 to 123). Thus the discipline began with the collection by venipuncture of whole blood, which required anticoagulation and storage at refrigerated temperatures. These procedures were optimized when it became possible to isolate different cell populations, such as red blood cells, platelets, and granulocytes. The term *blood banking* refers to collection and storage of blood products, both of which are highly regulated by the U.S. Food and Drug Administration (FDA).

The pioneering work by E. Donnall Thomas and others between 1950 and 1970, demonstrating the feasibility of transfusing bone marrow cells (i.e., bone marrow transplantation) as a treatment modality,[1,2] marked the next significant development of cellular therapies (see Chapters 104 to 110). The success of bone marrow engraftment is related to the presence of hematopoietic stem and progenitor cells in the bone marrow; immune cells in the graft, including T cells and NK cells, mediate graft-versus-tumor effects in patients transplanted for hematologic malignancy. Hematopoietic stem cell populations, currently used for therapy of malignant and nonmalignant disease, can be isolated from bone marrow, from (mobilized) peripheral blood, and from umbilical cord blood (see Chapter 96). An exciting new development in hematopoietic stem cell transplantation is the genetic manipulation/transduction of the hematopoietic stem cell to correct hereditary disorders such as the congenital immunodeficiencies and hemoglobinopathies[3] (see Chapter 99).

More recently, the ability to isolate and expand cell populations in culture has led to the evaluation of a number of cell therapy strategies. Only one approach, a dendritic cell vaccine, is currently approved by the FDA in the United States.[4] Infusions of other cells expanded ex vivo or significantly manipulated are conducted as experimental procedures through the FDA's Investigation of New Drug (IND) application process. Many such studies use autologous cells, which do not have a risk for transferring communicable disease but (because they are patient-specific products) make late-stage clinical trials more challenging. The use of allogeneic cells requires careful assessment of donor eligibility because of the risk for infectious disease transmission or transfer of immune reactivity[5] (Table 95-1). Allogeneic cells may also be used to produce a patient-specific product in some clinical settings, such as treatment of relapse postallogeneic transplant in which full HLA matching is required. In other applications, however, third-party cells may have benefits, including the advantage of broad applicability since a larger number of patients can receive a product generated from a single donor.

A broad range of cell types are currently being evaluated in clinical trials (see Chapters 97 to 103) Immune cell populations with distinct biologic properties are being infused to treat cancer and infectious diseases, and some approaches have progressed to late-phase testing (see Chapters 101 to 103). Nonhematopoietic stromal cells from bone marrow have attracted considerable interest recently for use in tissue repair and immunomodulation, largely because of their multilineage differentiation potential and their secretion of cytokines and chemokines (see Chapter 100). Their use, while experimental, is promising. Thus significant experience in cell-based therapies involving hematopoietic/bone marrow–derived cells has evolved, similar to blood banking and transfusion medicine, into a highly regulated discipline with oversight by several regulatory agencies, including the FDA and the NIH Recombinant DNA Advisory Board (see Chapters 97 and 98).

The next frontier of cellular therapies is being driven by the discovery and ability to culture stem cell populations from various other adult tissues (retina, cornea, heart, lung, etc.), embryonic stem cells, and inducible pluripotent stem cells. The therapeutic application of these cell populations, although intensely investigated worldwide, is regarded as preliminary at present.

Table 95-1 Evaluation of Allogeneic Donor for Eligibility to Provide Cell Therapy Product

Evaluation/Test*	Rationale/Purpose
Complete history and physical	To review the donor's medical and social history for risk factors for communicable disease agents and diseases. To review for clinical evidence of risk factors or diseases.
Donor questionnaire	To evaluate risk factors for communicable disease (using uniform donor questionnaire† drafted by international task force).
CBC, platelets, differential	To evaluate for evidence of hematologic abnormalities.
Electrolytes, BUN, creatinine, glucose, total protein, albumin, total bilirubin, alkaline phosphatase, ALT, AST, LDH	To evaluate for evidence of liver or electrolyte abnormalities.
ABO typing	To confirm identity.
HLA typing	To conduct HLA matching for some indications. To confirm identity.
HIV-1 antibody, HIV-2 antibody, HIV NAT, HTLV-1/2 antibodies, HBs antigen, HBc antibody, HCV NAT, CMV antibody, serologic test for syphilis (STS), West Nile virus NAT, Chagas disease (if indicated by region)	To exclude communicable disease agents. Must be collected at the time of recovery of the cells or tissue from the donor; or up to 7 days before or after recovery. For donors of peripheral blood stem/progenitor cells, oocytes and bone marrow may be collected for testing up to 30 days.

*The donor eligibility rule requires human cell and tissue products (HCT/Ps) establishments to screen and test cell and tissue donors for risk factors for, and clinical evidence of, relevant communicable disease agents or diseases. Additional IND-specific tests may also be mandated. All facilities need to use FDA-approved testing.
†Foundation for the Accreditation of Cellular Therapy (FACT) Standards: HPC Donor History Questionnaire (http://www.factwebsite.org/Inner.aspx?id=163&terms=donor+questionnaire).

CHAPTER 96

PRACTICAL ASPECTS OF HEMATOLOGIC STEM CELL HARVESTING AND MOBILIZATION

Scott D. Rowley and Michele L. Donato

Hematopoietic stem cell (HSC) products for autologous or allogeneic transplantation are available from bone marrow, peripheral blood, or umbilical cord blood (UCB) sources. Bone marrow was the original source of cells for transplantation because of the ease and reliability of collecting adequate numbers of cells for transplantation, and it remains the standard with which other sources of HSC are compared.

Peripheral blood stem cell (PBSC) products have virtually replaced bone marrow as the HSC component for autologous transplantation and are widely used for allogeneic transplantation. The rapid engraftment kinetics of PBSC compared with bone marrow is widely recognized. Median times to achieve an absolute neutrophil count greater than 500/μL and platelet transfusion independence after PBSC transplantation typically are approximately 11 to 14 days.[1-3] The improvement in engraftment kinetics reduces the cost of autologous transplantation (Table 96-1).[3-6] Although graft-versus-host disease (GVHD) prophylaxis with posttransplant methotrexate will slow engraftment, the kinetics of engraftment for the allogeneic PBSC recipient is similar to that experienced by the autologous PBSC recipient. A number of phase III studies involving either autologous or allogeneic HSC transplantation have confirmed the more rapid engraftment kinetics for recipients of PBSC (Table 96-2),[7-10] and this effect is not limited to HSC collected from the peripheral blood, because cytokine administration to the patient or donor before marrow harvesting will also increase the number of HSC collected and result in quicker hematologic recovery (Table 96-2).[11-13] The disadvantages to use of PBSC components compared with bone marrow or UCB for autologous or allogeneic transplantation include the usual need for multiple days of collection (especially for autologous transplantation), the inability to collect adequate components from all patients and donors, and a possibly higher risk for chronic GVHD or the occurrence of chronic GVHD that is more difficult to control[14] (see box on Choice of Hematologic Stem Cell Product for Transplantation).

UCB has found an important niche in the treatment of patients undergoing unrelated donor transplantation but who lack an appropriate related or unrelated volunteer donor. The relative immunologic naivete of the donor allows multiple-antigen mismatched transplantation without undue risks for acute or chronic GVHD.[15] The primary limitations of UCB transplantation derive from the small cell dose collected, which can result in a longer time to hematologic recovery and a higher risk for primary engraftment failure.

SELECTION AND EVALUATION OF THE STEM CELL DONOR

Selection of the Stem Cell Donor

The primary selection criterion for the patient undergoing autologous HSC collection and transplantation is the diagnosis of an illness amenable to treatment with a dose-intense regimen requiring HSC support. Extensive prior treatments, especially with marrow-toxic chemotherapy regimens, may preclude successful collection of autologous HSC, which would exclude a patient from this treatment option. In general, however, any comorbid illnesses that would preclude either marrow or PBSC collection would also disqualify the patient from treatment with dose-intensive regimens used in preparation for autologous HSC transplantation.

The selection of the allogeneic HSC donor is more complex. The HLA major histocompatibility complex (MHC) is the primary consideration in selection of a donor for allogeneic HSCT, since its loci contribute significantly to host-versus-graft (HVG, leading to immunologic rejection of donor HSC) responses and to graft-versus-host (GVH, leading to GVHD and GVL) reactions.[16,17] Donor age, gender, and parity are secondary considerations in the selection of an allogeneic HSC donor.[17,18] Mismatching for killer-cell immunoglobulin-like receptor (KIR) ligands may reduce the risk for posttransplant relapse of disease.[19] More than 30% of allogeneic HSC transplants from related or unrelated donors will involve ABO-disparate donor and recipients, and donor and recipient pairs may also differ for other red blood cell antigens, with no clear evidence of deleterious effect on engraftment, survival, or GVHD.[20] Cancer, autoimmune disorders, and genetic diseases such as the hemoglobinopathies can be transmitted to the allograft recipient; thus donor health is an important consideration in donor selection.

Evaluation of HSC Donors

The immediate precollection evaluation of a patient or donor is intended to address the risks of the collection procedure to the donor and the risks for transmission of disease from the donor. The same general donor health criteria apply to both bone marrow and PBSC donors. Patients undergoing autologous HSC collection and transplantation are not at risk for transmitting disease to themselves, but the laboratory must be notified of the infectious disease status of the patient because some viruses, particularly viruses with high infectious potency such as hepatitis B, can cross-contaminate other products stored in the liquid phase of nitrogen. All allogeneic HSC donors must be evaluated using the same criteria currently applied to blood donors, including a targeted history regarding behaviors exposing the donor to virus infection, recent or concurrent illnesses, and medication use.[21-24] This evaluation must be documented in the donor medical record with appropriate documentation of donor suitability in the recipient's medical record before initiation of the transplant conditioning regimen. Older donors will have more comorbid medical conditions, which will increase the risks of the collection procedures, and the risks to the donor with underlying health problems must be fully considered before subjecting the donor to HSC collection. Published standards describe evaluation of the donor for the risk of the donation process, as well as the risk for transmission of disease to the recipient.[21-23] Numerous infectious diseases that would not exclude the donor from blood donation, such as cytomegalovirus, may be transmitted with the allograft. However, donors who otherwise would be excluded for health reasons from donating blood for transfusion (e.g., individuals with a history of viral hepatitis) still may be selected to donate HSC if the needs of the recipient outweigh the risks and consequences of disease transmission. Evaluation by appropriate consultants may be required before donor approval is finalized. Procedures involving donors with acute infectious illnesses

Table 96-1 Costs of Autologous Transplantation by Source of Hematopoietic Stem Cell

Choice of Hematologic Stem Cell Product for Transplantation

Virtually all patients undergoing autologous HSC transplantation will have PBSC as the source of HSC, based on the following advantages: ease of collection, greater quantities of HSC (resulting in faster hematologic recovery and shorter and less costly hospital stays), and potentially lower risks for tumor cell contamination of the graft.

The allogeneic donor has a wider range of options, including marrow, PBSC, or UCB products from HLA-compatible or partially compatible related or unrelated donors. The transplant recipient may request a source of cells, but the donor has the right to decide about the method of donation. PBSC products have the greatest quantity of HSC and will result in faster hematologic recovery compared with marrow or UCB transplants. In some reports, PBSC transplantation also results in a survival advantage. However, PBSC transplantation is also associated with a higher risk for difficult-to-control chronic GVHD and may not be appropriate for use in patients who would not benefit from a robust GVL effect, such as those treated for nonmalignant diseases. Umbilical cord blood has the advantage of being immediately available, reducing the time to transplantation. Targeted collection of UCB products from ethnic populations not well represented in donor registries will facilitate treatment of ethnic minority patients. The relative immature immunity of the cord blood donor allows use of HLA mismatched products without an undue increase in GVHD risk. Infusion of two cord blood units may achieve a greater graft-versus-tumor effect, even though one unit will be rejected. The much smaller quantity of HSC in the cord blood product results in slower hematologic recovery, and the adult patient, in particular, may be at greater risk for post-transplant infections because of the relative immature immune system of the donor.

*Shown are number of patients enrolled in each arm of the study, quantity of $CD34^+$ cells × 10^6/kg (CFU-GM × 10^4/kg for reports by Beyer and Hartmann), days after transplantation to achieve a peripheral blood absolute neutrophil count >500/μL and platelet count >20,000/μL (25,000/μL for report by Blaise and 30,000/μL for report by Hartmann), and percentage of patients developing acute graft-versus-host disease.

Evaluation of the Marrow or Peripheral Blood Stem Cell Donor

HSC transplantation involves the infusion of a "blood product," and all donors must be evaluated for risks for disease transmission as per the current criteria for blood donation. Exemptions from criteria that specifically address the risk for disease transmission are permissible, if the risks of excluding an otherwise appropriate donor outweigh the risks for disease transmission to the transplant recipient, who may not have an alternate donor. Informed consent must be obtained for the evaluation and collection procedures. Informed consent also must be specifically obtained for the release of protected donor health information to the transplant recipient, allowing proper informed consent for the transplant to be obtained. Minors and donors not competent to provide consent must be represented by a third party not involved in the care of the recipient. Ideally, similar courtesy will be provided to the adult donor. Donors must also be evaluated for health issues that would increase the risks resulting from the collection procedures. For marrow donors, this includes the risks of anesthesia; for PBSC donors, evaluation should include the risks of mobilization medications and apheresis.

The donor collection facility's standard operating procedures for evaluation of HSC donors must meet FACT/JACIE or AABB guidelines and FDA (or other regulatory agency) standards, and include policies and procedures for the following:

- Education of donor, including education regarding procedures, risks, alternatives, and possible future collections
- Medical history, including special attention to history of autoimmune disorders, arthritis, cardiac and vascular diseases, and history of cancer
- History of high-risk behaviors, such as recent tattoos, body piercing, sexual practices, and travel
- Physical examination, including vein assessment (PBSC donors) and oral examination (marrow donors undergoing inhalational anesthesia)
- Laboratory studies, including verification HLA typing, ABO typing, CBC, chemistry panel, infectious disease panel, urinalysis, ECG, CXR
- Consent for collection procedures and the release of protected health information to the stem cell recipient

should be delayed, if at all possible, because of the risk for disease transmission. Genetic disorders, such as hemoglobinopathies, will be transmitted to the recipient as a direct consequence of stem cell engraftment. Cancer can be transmitted, as illustrated by the transmission of donor leukemia not detected during initial evaluation of the donor,[25] and donors previously treated for cancer should be evaluated for the probability of recurrent disease that could be transferred to the immunocompromised recipient.[26] Collection of PBSC is generally an outpatient procedure conducted in the clinic setting. In contrast, marrow harvesting has the luxury of the intensive support capability of the operating room. PBSC collection should never be viewed as a safer alternative to marrow harvesting for the donor with underlying health problems. Pediatric donors present different challenges, based on the smaller size and varying ages (and ability to cooperate) of the donors (see box on Evaluation of the Marrow or Peripheral Blood Stem Cell Donor).

Use of a donor who does not meet eligibility criteria and who poses a risk for transmission of disease requires appropriate informed consent both from the donor (for disclosure of this confidential health information to the recipient and for counseling of the recipient) and from the recipient (for use of the stem cell product). The potential conflict of interest between protecting donor health and patient needs must be recognized, and preferably, the donor and patient should be represented by different physicians.[27]

Specific Evaluation of Bone Marrow Donors

Anesthesia and blood loss present the greatest risks for serious complications to the bone marrow donor. Most marrow harvesting is performed under general anesthesia, which requires intubation for control of the airway for a surgical procedure performed on a prone patient. Regional (spinal or epidural) anesthesia may not be effectively established, so patients and donors who express a preference for this anesthesia must be counseled about the potential need for general anesthesia. The health assessment must include questioning about a history of joint disease of the cervical spine and mandible and examination of the mouth if general anesthesia requiring intubation is chosen. Patients and donors with comorbid conditions, such as aortic stenosis sensitive to changes in blood volume and blood pressure, may require anesthesia consultation and plans for invasive monitoring during the surgical procedure. A history of marrow fibrosis, pelvic irradiation, or pelvic tumor involvement may exclude a patient from marrow harvesting, although unilateral harvesting from the posterior and iliac crests and aspiration of the sternum may achieve adequate quantities of cells for transplantation.

Specific Evaluation of Peripheral Blood Stem Cell Donors

The PBSC donor is exposed to the risks of cytokine (and chemokine) administration and the risks related to the apheresis procedure, including the risks of central venous catheter insertion and use. No long-term health consequences have been associated with cytokine administration, and the specific toxicities with these agents are described later. Filgrastim may lead to a flare of autoimmune disorders and may increase the risk for blood clots, particularly for donors who are sedentary or who may be traveling shortly after the donation procedures.[28] The PBSC donor must be assessed for venous access before the patient receives conditioning, and consent for use of a central venous catheter must be obtained if the venous access is deemed inadequate for the apheresis procedure.

Specific Evaluation of Umbilical Cord Blood Donors

Evaluation of the donor for UCB donation begins with a history of maternal (and paternal) illness and exposures to infectious diseases. A comprehensive genetic and family history should be obtained. Although linkage between the infant and the product is currently maintained, an update of infant health is not obtained at the time of transplantation, which may be several years after collection. Parental medical history includes specific questions addressing the risks for transmission of hereditary or acquired blood-borne diseases. Testing for infectious diseases is obtained from the mother at the time of collection to minimize loss of product.

Public UCB banks set criteria for the storage of units in order to avoid the collection and storage of UCB units that would not be acceptable for transplantation.[29] Exclusion criteria for potential donors in one multicenter study, for example, included the following: multiple gestation; premature delivery; active chorioamnionitis or sepsis; mother being the recipient of an organ transplant; mother with history of cancer; mother with high-risk behaviors or previously diagnosed with HIV, hepatitis, or syphilis; and mother having active venereal disease such as vaginal herpes simplex and delivering vaginally.

COLLECTION OF BONE MARROW FOR TRANSPLANTATION

Bone Marrow Collection Techniques

Bone marrow typically is harvested from the posterior iliac crests using virtually the same techniques used to obtain diagnostic samples

in the clinic. The primary differences between obtaining diagnostic specimens and cell quantities adequate for transplantation are the volume of blood and marrow removed, which requires attention to fluid replacement during the procedure, and the need for appropriate anesthesia. Bone marrow harvesting from healthy donors presents little risk for serious morbidity, permitting the ethical recruitment of allogeneic donors, including unrelated and pediatric bone marrow donors.[21] Multiple aspirations are performed with collection of approximately 5 mL of marrow from each puncture site. If properly spaced, no more than two to three skin puncture sites per side usually are required. Other harvest sites, such as the anterior iliac crests or sternum, can be used, but at increased risk for complications from accidental laceration or perforation of contiguous anatomic structures. For patients with a history of radiation or tumor involvement of one pelvic crest, adequate cells can be harvested from the anterior and posterior crests of the other side.

Marrow is collected in the day surgery suite using either general or regional anesthesia. With proper fluid and blood replacement, overnight hospitalization should not be required. For the healthy donor, the risks for serious complications from either general or regional anesthesia are minimal, although a multivariate analysis of adverse events performed by the National Marrow Donor Program (NMDP) for unrelated donors reported a higher risk for serious adverse events for donors receiving regional anesthesia.[30] Use of spinal or epidural anesthesia avoids the nausea that may occur with general anesthesia, especially for younger women, but hypotension from loss of vascular tone in the lower extremities often occurs as the volume of marrow is collected. General anesthesia is preferable for the donor with comorbid disorders such as cardiovascular or cerebral vascular disease because of the better control of donor airway and lower risk for hypotension during the harvest procedures. Local anesthesia is acceptable only if a very limited harvest is being performed, because local anesthesia does not achieve anesthesia of the marrow space and because large quantities of lidocaine, for example, are cardiotoxic.

Both heparin and acid-citrate-dextran–A (ACD-A) can be used for anticoagulation of bone marrow products. ACD-A decreases the accumulation of lactic acid and may be preferable, especially for products that will be transported or stored for longer periods before infusion or cryopreservation.[31]

Toxicity of Bone Marrow Collection

Anesthesia complications present the major health risk to the donor; marrow aspiration is generally well tolerated, although postharvest discomfort is experienced to some extent by all donors.[32] Complications include hemorrhage and infections at skin puncture sites. Severe hematomas and neuralgias rarely occur, and attention to pelvic anatomy is required to decrease the risk for damage to vessels and nerves lying under or adjacent to the iliac crest harvest sites. Irritation of the sacral nerves may result from needle penetration through the pelvic bone or from blood tracking into the nerve roots and requires several months of convalescence. Localized pain is common, may last for several days, and may require a brief period of medication with opioid/acetaminophen combinations. In a survey of over 9000 donors for unrelated bone marrow transplantation, 82% reported collection site pain, with a median time to recovery of 3 weeks.[30] Pain associated with the anesthesia procedures (throat pain, 33%; postanesthesia headache, 17%) was reported by a large proportion of the donors. Fatigue was reported by 59% of donors. Serious adverse effects were reported for 125 donors (1.35%), with 116 donors reporting serious complications considered to be associated with the collection procedures. Most serious complications ($n = 69$) were due to mechanical injury to tissue, bone, or nerve, and a smaller but similar number ($n = 45$) were related to anesthesia. Infection and grand mal seizure were reported for one donor each. A retrospective survey of donor events reported by the European Group for Blood and Marrow Transplantation described almost 28,000 bone marrow donors, with one death from pulmonary embolism.[33] An additional 12 donors experienced severe adverse events, including four cardiac arrests (three during anesthesia), two episodes of severe hypertension, one pulmonary embolism from heparin-induced thrombocytopenia, one episode of pulmonary edema, one donor with a subdural hematoma, and three events not otherwise specified. This retrospective survey did not include all donors and may have underreported adverse events. This report, furthermore, did not report the experiences of related and unrelated donors separately. The risks reported for healthy donors reported by unrelated donor registries may underestimate the risks faced by donors for related recipients, who may undergo collection despite comorbid illnesses that would preclude participation in an unrelated donor registry. Most donors are able to return to routine activities 1 to 2 days after harvesting, although the recovery time for the 67 donors reporting serious mechanical injury was a median of 10 months (range, 1 to 96 months).[30]

The usual volume harvested from healthy donors is approximately 10 to 15 mL of marrow per kilogram of recipient body weight to achieve the desired nucleated cell and $CD34^+$ cell doses. This results in a blood loss of 800 to 1000 mL for donors providing marrow for an average-sized adult recipient. The quantity of marrow harvested from autologous patients may be greater, reflecting previous chemotherapy given to these patients. Donors for pediatric recipients will lose proportionately less blood. Most patients and donors receive blood transfusions to alleviate symptoms of volume depletion. With proper preharvest autologous blood storage, use of homologous blood for healthy first-time allogeneic donors should be extremely rare. For a blood loss of less than 10 mL/kg of donor weight, salt solutions are acceptable for volume replacement. Colloid solutions, such as hydroxyethyl starch, also can be used to avoid homologous blood transfusion for blood losses between 10 and 20 mL/kg donor weight. Blood transfusion will be required for larger blood losses (>20 mL/kg) or for patients with comorbid illnesses. Homologous blood transfusions must be irradiated to prevent transfusion-associated GVHD in the transplant recipient. Donors undergoing second harvest shortly after the first harvest are more likely to require homologous blood.[23] Oral iron supplements should be considered for healthy donors, particularly for female donors or donors from whom a large blood volume is to be harvested.

COLLECTION OF UMBILICAL CORD BLOOD STEM CELLS FOR TRANSPLANTATION

Cord Blood Collection Techniques

Advantages of this source of HSC include the ability of public cord blood banks to target collections from ethnic minority populations not well represented in the various unrelated donor registries and the relative immaturity of the donor immune system allowing transplantation of HLA mismatched units without overwhelming GVHD. The primary obstacle to the widespread use of cord blood cells is the limited quantity of HSC collected, and one public UCB bank predicted that from less than 5% to less than 38% (depending on the cell dose criterion for transplantation) of the units stored in that bank would be acceptable for transplantation of an 80-kg adult patient.[34] The speed and success of engraftment are predicted by the total nucleated cell dose and, more important, by the quantity of $CD34^+$ cells or infused colony-forming units (CFUs).[35]

UCB is collected from the placental vein after delivery of the infant and transection of the cord, either before delivery of the placenta by the obstetrician or by laboratory personnel after delivery of the placenta.[34] Published reports conflict regarding the volume of UCB collected and the likelihood of obtaining a product inadequate for storage with either in utero or ex utero collection. The timing of cord clamping after delivery of the infant is associated with the volume of cord blood collected, and greater volumes are collected with earlier clamping. Greater cell quantities were found for infants with greater birth weight, but no difference was found based on gender or gestational age. Ethnic background appears to predict the cell quantities, with smaller quantities of cells collected from ethnic

minorities compared with whites.[36] UCB usually is collected by cannulation of the umbilical cord veins with aspiration of the blood into a collection bag. Collection of cord blood into open containers results in an unacceptable rate of bacterial contamination. Perfusion of the placenta with salt solutions may increase the cell number collected, but this has not been widely adopted. Many cord blood banks reduce the volume of the product by red cell and plasma depletion to minimize storage space and to reduce possible infusion-related toxicities from mature blood cells contained in unfractionated cord blood units.[37] Bacterial contamination of UCB products is of concern, especially in the collection of products for related donor transplantation by obstetricians with limited or no experience in HSC collection and processing.[38] The identification and evaluation of the donor and the collection techniques used should be viewed as the first step in a manufacturing process with adequately validated procedures, personnel training, quality control, and performance improvement oversight.

COLLECTION OF PERIPHERAL BLOOD STEM CELLS FOR TRANSPLANTATION

Background

The presence of HSC in the peripheral circulation was suggested by animal studies as early as 1951.[39] Although the nature of the survival agent was not recognized at that time, parabiosis experiments demonstrated that some factor in the blood of a healthy animal was able to rescue another animal from the effects of lethal irradiation. Subsequently, a number of animal models demonstrated the presence of HSC in the peripheral blood and the successful use of these cells to rescue animals from the marrow-lethal effects of radiation. The concentration of HSC in the peripheral blood normally is very low, requiring the processing of large quantities of blood to collect the quantity of HSC equivalent to what could be collected in a bone marrow harvest. For this reason, PBSC transplantation initially was limited to a few transplant programs that explored this source of HSC for patients who otherwise were ineligible for marrow harvesting, collecting cells during steady-state hematopoiesis or during the transient increase in circulating HSC that occurred during recovery from marrow hypoplasia-producing chemotherapy.[40-44] These early reports noted that engraftment could be achieved sooner after infusion of PBSC components compared with marrow cell transplantation. However, because of the occasionally limited quantity of HSC that was collected from the peripheral blood, the kinetics of engraftment for some patients was considerably slower (Table 96-3). The effective mobilization of HSC achieved by cytokine or chemokine administration[45-47] and the reliability of same-day flow cytometric analysis in assessing the quality of the collection are the direct bases for the rapid and widespread adoption of PBSC as a source of HSC for transplantation (see box on Mobilization and Collection of Peripheral Blood Stem Cell for Autologous Transplantation).

Cytokine-mobilized PBSC components contain much greater numbers of cells expressing the CD34 antigen ($CD34^+$ cells), which, along with myeloid progenitor cells grown in culture (CFU-GM), serve as surrogate markers for the engraftment capacity of the stem cell component. The dose of $CD34^+$ cells infused predicts the kinetics of engraftment (Figs. 96-1 and 96-2). Patient groups that receive higher quantities show a higher probability of quicker recovery of

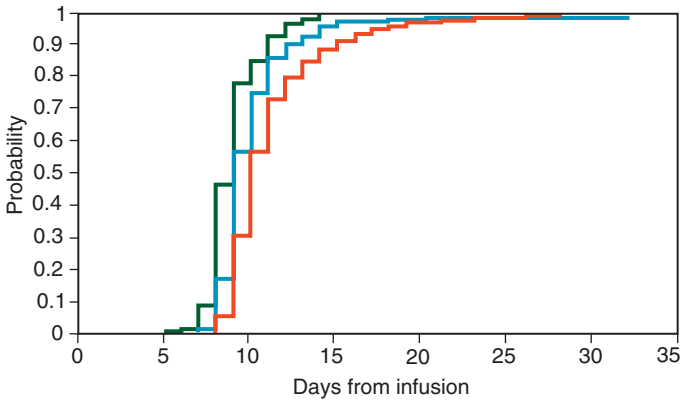

Figure 96-1 Kaplan-Meier probability of achieving $\geq 0.5 \times 10^9$ neutrophils/L for $<5.0 \times 10^6$ (–), >5.0 to 10.0×10^6 (..), and $>10 \times 10^6$ (—) $CD34^+$ cells per kilogram ($P = 0.0001$). *(From Weaver CH, Hazelton B, Birch R, et al: An analysis of engraftment kinetics as a function of the CD34 content of peripheral blood progenitor cell collections in 692 patients after the administration of myeloablative chemotherapy.* Blood *86:3961, 1995.)*

Mobilization and Collection of Peripheral Blood Stem Cell for Autologous Transplantation

Four important considerations when prescribing a mobilization regimen for collection of PBSC for autologous transplantation are as follows: (1) A regimen of chemotherapy followed by G-CSF results in higher numbers of circulating $CD34^+$ cells than will be found with G-CSF alone. (2) The choice of chemotherapy (or cytokine alone mobilization) should be appropriate to the disease and stage of disease for the patient. (3) Each cycle of prior chemotherapy and any previous treatment with radiotherapy will decrease the response to mobilization therapy. (4) Tumor infiltration of the marrow will increase the probability of circulating tumor cells and will decrease the response to mobilization therapy. With these considerations in mind, elective collection of PBSC either before extensive treatment or after a limited number of cycles of debulking chemotherapy should be considered. If tumor contamination is found, additional components can be collected after additional rounds of chemotherapy. The timing of apheresis after chemotherapy and G-CSF mobilization is best guided by measurement of the level of peripheral blood $CD34^+$ cells. Daily or every-other-day quantification of these cells can be initiated after the WBC count reaches 1000/μL. Patients with poor mobilization of $CD34^+$ cells should be considered for large-volume apheresis or addition of plerixafor to reduce the costs associated with daily doses of G-CSF, laboratory testing, apheresis procedures, and cryopreservation. Patients who fail to mobilize may have successful collections if given a short drug holiday before undergoing mobilization with high-dose G-CSF with plerixafor.

neutrophil and platelet counts.[46,47] Although PBSC products containing at least 1 × 10^6 to 2 × 10^6 $CD34^+$ cells per kilogram of recipient weight will achieve hematopoietic stem cell reconstitution, for most patients, cell doses of 2.5 × 10^6 to 5 × 10^6 $CD34^+$ cells per kilogram are desirable, and quicker and more uniform neutrophil and platelet recoveries will be observed with even higher doses.[46,47]

Mobilization of Hematopoietic Stem Cells into Peripheral Blood

The self-renewal and differentiation of HSC is controlled by the surrounding microenvironment of the stem cell niche(s) in which the HSC reside.[48] These niches are composed of a complex three-dimensional architecture of a variety of cell types including sinusoidal endothelial cells, sympathetic nerve fibers, cells of the osteoblastic lineage, macrophages, and mesenchymal stem cells that are responsible for controlling the balance between HSC quiescence, self-renewal, and differentiation. A number of pathways with mutually recognized cellular adhesion molecules and their respective ligands responsible for the spontaneous migration of HSC from the stem cell niche, as well as the multistep process of homing back into the niche, have been identified.[49] The mechanisms by which G-CSF and other cytokines promote mobilization of HSC are being elucidated and appear to be an indirect effect (HSC do not express receptors for G-CSF) on the CXCR4/SDF-1 axis mediated by monocytes and the sympathetic nervous system.[48] The mechanisms of mobilization by chemotherapy and CXCR4 antagonists such as plerixafor are also being determined, and the elucidation of the mechanisms of mobilization and homing may result in more effective harvesting and transplantation techniques.[50]

Cytokine Mobilization

The ability of recombinant hematopoietic cytokines to increase the level of myeloid progenitor cells in the blood, as well as mature blood cells, was reported in 1988 by different groups for both G-CSF and GM-CSF.[51,52] Subsequently, a number of different investigators reported the collection of PBSC from patients using a variety of mobilization regimens, including cytokines alone, cytokine combinations, and combinations of chemotherapy with cytokines (Table 96-2). Various other recombinant human hematopoietic cytokines, including fusion molecules, increase the quantity of $CD34^+$ cells in the peripheral blood, but have not been developed for clinical transplantation.

Granulocyte Colony-Stimulating Factor

G-CSF is the cytokine most commonly used because of its efficacy compared with other cytokines and its relatively benign toxicity profile. Recombinant methionyl human G-CSF (filgrastim) and recombinant human G-CSF (lenograstim) are the two forms of this cytokine available for clinical use.[53] There is slight, if any, difference between these two cytokines in their ability to mobilize PBSC. Watts and colleagues studied 20 healthy volunteers and found that peak levels of CFU-GM in the peripheral blood were 28% higher after treatment with the glycosylated molecule (lenograstim), likely resulting from the higher specific activity of this form.[54] De Arriba and colleagues treated 30 women with breast cancer in a randomized study of these two drugs, using dosages containing bioequivalent units of activity and found no difference in mobilization of $CD34^+$ cells.[55] The two forms have otherwise similar biologic activity and are not further distinguished in this discussion.

Mobilization of Hematopoietic Stem Cells Using Granulocyte Colony-Stimulating Factor

G-CSF is the most potent cytokine currently available for mobilization of HSC. In a randomized study of healthy volunteers comparing G-CSF, GM-CSF, and the combination of both, Lane and colleagues reported an average 0.99% $CD34^+$ cells in the peripheral blood of healthy donors treated with 10 μg/kg/day of G-CSF compared with 0.25% for donors treated with the same dose of GM-CSF.[56] The quantity of $CD34^+$ cells in the peripheral blood before treatment averaged 1.6/μL. After GM-CSF treatment, the level increased to 3/μL, but with G-CSF, the level increased to 61/μL. Each group underwent one leukapheresis on the fifth day of treatment, and the collections from donors treated with G-CSF averaged 119 × 10^6 $CD34^+$ cells compared with 12.6 × 10^6 for the donors treated with GM-CSF.

The appearance of $CD34^+$ cells during administration of G-CSF follows a distinct time course, with the maximal level of $CD34^+$ cells occurring on day 5 after daily G-CSF administration.[57] Smaller numbers of $CD34^+$ are present on days 4 and 6, and the level falls rapidly on subsequent days despite a continual rise in white blood cell (WBC) count.

The number of $CD34^+$ cells collected after G-CSF treatment is proportional to the number of these cells in the peripheral blood before initiation of the cytokine.[17] Although doses as low as 5 mcg/kg/day have been used, there is a dose response to G-CSF, with higher average levels of $CD34^+$ cells achieved with 10 mcg/kg/day compared with 5 mcg/kg/day.[58] With appropriate dosing of allogeneic donors, adequate numbers of $CD34^+$ cells can be collected in one procedure for transplantation of most patients. A similar dose response is observed in autologous patients and may extend to doses as high as 40 mcg/kg/day.[58] An advantage to twice daily dosing of G-CSF has been suggested but not confirmed. Anderlini and colleagues compared administration of 6 mcg/kg given twice daily with 12 mcg/kg given once daily and found no differences in $CD34^+$ cells per liter of blood processed or the yield of $CD34^+$ cells per kilogram collected.[59] In contrast, a second trial enrolling primarily pediatric subjects noted better results with the twice-daily schedule.[60] Patients, especially those previously treated with chemotherapy or radiotherapy, will generally have lower quantities of $CD34^+$ cells mobilized.[50]

Toxicity and Complications of Granulocyte Colony-Stimulating Factor

The toxicity of G-CSF has been most clearly defined in studies of allogeneic donors.[28,61,62] The autologous patient will experience a similar toxicity profile, but with the added complications of the underlying malignancy and its treatment.

Almost all recipients of G-CSF will develop somatic complaints, of which skeletal pain is most prominent (Table 96-4). The somatic complaints are generally tolerable, and few donors will require reduction in dose or discontinuation of the medicine. At present, there appear to be minimal, if any, long-term health risks for the donor. Few serious complications of the mobilization regimen and donation process have been reported.[63] Filgrastim increases spleen size, with a rare patient or donor experiencing splenic rupture. Filgrastim induces a hypercoagulable state, which is of concern for donors (and patients) requiring central venous catheter placement or for those who may have other risk factors for the development of deep venous thrombosis (such as air travel immediately after the collection procedures). Patients with autoimmune disorders may experience a flare-up of their disease during administration of G-CSF, and a variety of case reports of ophthalmologic and other adverse events have been reported for healthy donors or patients treated with G-CSF.

Of concern is the possibility that cytokine administration will increase the risk for marrow dysplasia or malignancy. Although this is a theoretical concern in that the cytokines used are known to stimulate growth of leukemia cells, no clinical evidence (such as that reported in the large registry reviews of healthy donor experiences) indicates that these agents will induce abnormalities in the hematopoietic cell.[63]

G-CSF administration results in a number of changes in blood counts and chemistries in addition to the coagulation factor changes. Alanine aminotransferase, lactate dehydrogenase, and alkaline phosphatase levels increase, and the levels of blood urea nitrogen and bilirubin may decrease.[62] The elevation in alkaline phosphatase level is primarily of bone origin; γ-glutamyl transferase levels remain normal. These abnormalities of serum chemistries resolve within 2 weeks after discontinuation of the medication. G-CSF administration also will result in a decrease in platelet count, especially if the cytokine is administered over 5 to 10 days.[62] WBC counts fall rapidly after discontinuation of G-CSF. In approximately 10% of donors, the WBC count may fall to abnormal levels (but generally still remaining above 1000/μL), reaching a nadir 10 to 14 days after discontinuation of the cytokine before stabilizing at normal levels.

Table 96-4 Incidence of Somatic Complaints for Normal Donors Treated With Granulocyte Colony-Stimulating Factor

	Anderlini et al[28]	Bishop et al[61]	Stroncek[62]
No. of donors	43	41	85
G-CSF dose (mcg/kg/day)	6	5	2-10
Symptoms (%)*			
Malaise	82	83	86
Headache	70	44	28
Fatigue	20	NR	14
Fever	0	27	NR
Chills	NR	22	NR
Nausea	10	22	11

G-CSF, Granulocyte colony-stimulating factor; *NR*, particular complaint not reported in this series.
*Shown are reported proportions of donors experiencing the listed somatic complaint.

Granulocyte-Macrophage Colony-Stimulating Factor

Much of the early experience with the use of hematopoietic cytokines for mobilization of HSC involved GM-CSF and chemotherapy.[52,64] GM-CSF is not as potent as G-CSF,[56,64] although as with G-CSF, there is a dose response in mobilization of PBSC with GM-CSF over a range from 0.3 to 20 mcg/kg/day, without a plateau.[65] In this dose-ranging study, however, the average increase in CFU-GM in the blood at this highest dose level again was only 8.4-fold. In a randomized study comparing GM-CSF with G-CSF, or both drugs used in sequence after chemotherapy administration, patients had faster recovery of counts, required less supportive care including transfusions, and achieved greater collections of $CD34^+$ cells if given one of the G-CSF–containing regimens.[64]

Administration of GM-CSF results in somatic complaints and hepatic function abnormalities similar to those reported after G-CSF administration. In addition, 44% to 80% of patients experience fever, sometimes after each dose, as well as generalized or local skin reactions. Doses greater than 20 mcg/kg/day are poorly tolerated because of fluid retention, pleural and pericardial inflammation, and venous thrombosis. A "first-dose reaction," characterized by hypoxia and hypotension occurring within 3 hours of administration, has been described for some recipients, especially after IV administration.

Other Hematopoietic Cytokines

Recognition of the mobilization potential of G-CSF led many investigators to study other hematopoietic cytokines, including erythropoietin, monocyte–colony-stimulating factor (M-CSF), interleukin-3, PIXY 321 (a fusion molecule), and stem cell factor (SCF) for their capacity to mobilize HSC into the peripheral blood. Used as single agents, these cytokines resulted in only an approximately 5- to 10-fold increase in circulating CFU-GM or $CD34^+$ cells. Only SCF is approved for human use (in Europe), and none of these cytokines are widely used in clinical HSC transplantation.

Chemotherapy Plus Cytokine Mobilization

The number of HSC in the peripheral blood is greatly increased during the early hematologic recovery phase after marrow hypoplasia-producing chemotherapy (Table 96-3). Moreover, chemotherapy plus

cytokine generally mobilizes greater numbers of PBSC than either agent alone. This finding was confirmed in a randomized study comparing cyclophosphamide followed by G-CSF versus G-CSF alone, in which higher numbers of CD34 cells were found for the patients treated with the chemotherapy-based regimen.[66] However, no differences in the degree of tumor cell contamination of PBSC components, engraftment kinetics, or survival were found. A wide variety of different chemotherapy regimens has been used successfully for mobilization of HSC into the blood, with cyclophosphamide- or ifosfamide-based regimens being most commonly used. The primary consideration is that the choice of chemotherapy used must meet the treatment needs of the patient. However, the choice of chemotherapy regimen can affect the mobilization of HSC. Demirer and colleagues studied the effect of different chemotherapy regimens for mobilization of HSC for patients with breast cancer.[67] Four regimens were used, all involving CY, but including etoposide with or without cisplatin, or paclitaxel. All patients also received G-CSF. The median quantity of $CD34^+$ cells collected on the first day of apheresis after cyclophosphamide mobilization was 0.9×10^6 per kilogram of patient weight. The addition of etoposide and then of etoposide and cisplatin increased the first-day yield to 8.1×10^6 and 3.5×10^6 $CD34^+$ cells per kilogram, respectively, in separate cohorts of patients. The median number of $CD34^+$ cells harvested on the first day of apheresis after cyclophosphamide plus paclitaxel was 11.1×10^6/kg, and more than 50% of the women mobilized with this last regimen achieved the target dose of $CD34^+$ cells in one apheresis procedure. Of the 100 women studied, 94 achieved the target dose of greater than 5×10^6 $CD34^+$ cells per kilogram. Only four patients failed to reach a lower but acceptable dose of 2.5×10^6 $CD34^+$ cells per kilogram.

Chemokines

Chemokines (chemoattractant cytokines) are a family of approximately 40 related small proteins that influence leukocyte (and malignant cell) migration and function.[68] Chemokines with varying effects on different WBC populations have been identified, as have a number of chemokine receptors. The roles of chemokines and chemokine receptors in the trafficking of HSC into and from the bone marrow compartment are under active investigation.[69]

In a preclinical study, administration to both mice and rhesus monkeys of a modified CXC chemokine GRO-β after 4 days of G-CSF resulted in a fivefold increase in the number of circulating stem and progenitor cells compared with G-CSF alone, with also a much shorter time course of release, measured in hours.[70] Furthermore, more rapid recovery of hematopoietic function was observed for animals given similar quantities of cells collected after administration of the chemokine and cytokine combination. IL-8, a related ligand for the CXCR2 receptor, mobilizes stem cells within 15 to 30 minutes of injection into mice,[71] which appears to involve increased matrix metalloproteinase-9 activity detectable immediately before the appearance of HSC in the peripheral circulation. Murine studies demonstrate a mobilizing effect of the chemokine SDF-1 and its receptor CXCR4 that can be blocked by neutralizing antibodies to either.[71] The bicyclam molecule plerixafor disrupts SDF-1/CXCR4 binding and has been shown to result in mobilization of HSC in murine, canine, and nonhuman transplant models.

Similar signaling pathways are used for mobilization and homing of normal and malignant hematopoietic cells.[72] Although PBSC products collected after G-CSF mobilization generally contain fewer detectable tumor cells than does bone marrow harvested from the same patient, the effects of chemokine treatment on the degree of PBSC contamination and on disease relapse after autologous transplantation remain to be elucidated. For example, acute myelogenous leukemia cells express CXCR4 in varying levels and homing of primary human AML cells into NOD/SCID mice is CXCR4 dependent, similar to normal human stem cells. Similar studies of chemokine control on tumor cell growth, migration, and metastasis are being reported from a number of laboratories.

Plerixafor

Plerixafor is a small molecule inhibitor of CXCR4. Clinical studies of HSC mobilization using plerixafor (AMD3100) with or without G-CSF priming are being reported in both healthy donors and patients undergoing autologous or allogeneic HSC transplantation. In a study involving normal volunteers, a single dose of plerixafor was equal in mobilization of $CD34^+$ cells to administration of a standard 5-day course of G-CSF.[73] However, a single dose of plerixafor given on day 5 of a daily course of G-CSF administration resulted in a further 3.8-fold increase in circulating $CD34^+$ cells (as well as B and T cells, which may be important in allogeneic transplantation). Randomized phase III studies conducted in patients undergoing autologous PBSC transplantation in the treatment of multiple myeloma or non-Hodgkin lymphoma demonstrated a clear increase in $CD34^+$ cells collected by the addition of plerixafor to filgrastim.[74,75] Plerixafor was also effective in remobilization attempts for patients who failed initial collection goals.[76] Plerixafor clearance is proportional to degree of renal function in patients with renal failure.[77] Minor gastrointestinal symptoms appear to be the most common toxicities of this medication.

Strategies for the Patient Who Is Difficult to Mobilize

Most patients achieve the targeted dose of $CD34^+$ cells after processing 20 to 30 L of blood in one to three apheresis procedures. However, approximately 5% to as many as 30% of patients in various series have inadequate collections because only small numbers of HSC are present in the peripheral blood despite the administration of hematopoietic cytokines. Of note, the number of days of apheresis separately predicts the kinetics of neutrophil engraftment beyond the $CD34^+$ cell dose, indicating an undefined measurement of graft quality, probably a reflection of the various quantities of $CD34^+$ cell subsets and $CD34^-$ stem cells.[78] Patient-specific factors predictive of poor mobilization include older age, marrow disease, prior radiotherapy, and prior chemotherapy.[50] Approximately 50% of patients who fail to achieve the targeted dose of $CD34^+$ cells will achieve this goal on a second attempt. High-dose (15 mg/kg bid) G-CSF after a 2- to 4-week drug holiday to allow marrow recovery is one strategy. Combination cytokine therapy is also of potential value in this situation, and the combination of SCF with G-CSF may be effective for patients who reside in countries where SCF is available. The addition of GM-CSF to G-CSF is not of proven value. Initial experience with plerixafor suggests that the agent will often be effective when used in combination with G-CSF for collection of PBSC from patients who failed a prior mobilization attempt.[76] Treatment with a use of cyclophosphamide- or ifosfamide-based mobilizing chemotherapy plus cytokine regimen also will be effective but may be associated with increased toxicity.[79] Bone marrow can be harvested, but the poor mobilization of PBSC predicts for a poor marrow harvest. Patients who fail initial collection attempts frequently will fail subsequent attempts, and transplantation of these patients with a lower dose of $CD34^+$ cells (as low as 1×10^6 $CD34^+$ cells per kilogram) may be an option.

It is preferable to avoid collection failure. Consideration should be given to the prophylactic collection of PBSC early in the course of treatment for patients who later may be candidates for autologous HSC transplantation but who are advised to receive multiple courses of therapy or therapy involving alkylating agents or radiation therapy. HSC can be collected and cryopreserved before extensive therapy while the patient has good marrow function and stored for years without obvious progressive loss of engraftment potential.

Timing of Apheresis

A major problem with chemotherapy-based mobilization regimens is the difficulty in determining the optimal time to commence HSC collection. Apheresis devices can collect only those $CD34^+$ cells actually being released into and circulating in the peripheral blood. It is

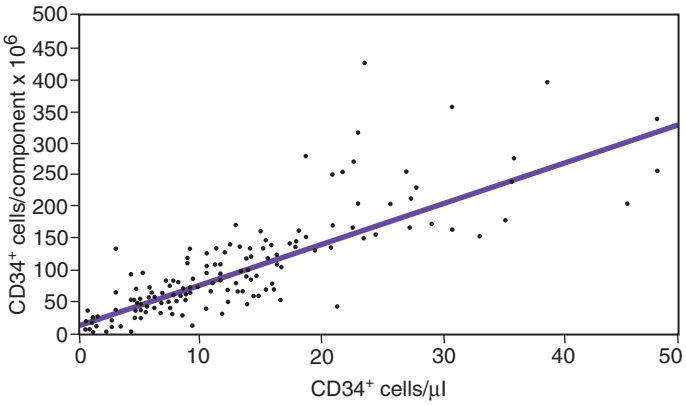

Figure 96-3 Relationship between quantity of $CD34^+$ cells in the peripheral blood and number collected by apheresis using apheresis and flow cytometric techniques. Data shown are limited to peripheral blood $CD34^+$ cell numbers <50.0/μL ($n = 157$, $r = 0.82$, $P < 0.001$).

possible to estimate the quantity of $CD34^+$ cells that will be collected during apheresis by multiplying the quantity of $CD34^+$ cells in the blood by the total volume of blood processed during the apheresis procedure and by the efficiency of the apheresis device in collecting these cells. If the device has an efficiency of 50% and the patient undergoes a 10-L exchange, approximately 5×10^7 $CD34^+$ cells will be collected for a peripheral blood level of 10 $CD34^+$ cells per microliter and 5×10^8 $CD34^+$ cells for a blood level of $CD34^+$ cells that is 10-fold higher. Although many protocols call for initiation of apheresis after chemotherapy mobilization when the WBC count has recovered to greater than 1000/μL, there is a poor, if any, correlation between the peripheral blood white cell or mononuclear cell counts and the $CD34^+$ cells in the peripheral blood. Characteristics that suggest a higher $CD34^+$ cell level are a rapidly rising WBC count, shift in differential to immature myeloid cells, circulating nucleated red cells, and platelet transfusion independence. However, it is much more cost effective to obtain an actual measurement of $CD34^+$ cells in the blood and to time the apheresis collection when these cells are present in adequate numbers. Fig. 96-3 shows such a relationship for patients with lower concentrations of $CD34^+$ cells in the peripheral blood and illustrates the very poor collections obtained when the peripheral blood $CD34^+$ count is less than 10/μL. Although there is considerable error in the enumeration of $CD34^+$ cells at levels less than 5/μL, this error is not clinically relevant because even a doubling of the $CD34^+$ cells in this low range still results in a very poor apheresis yield.

The level of $CD34^+$ cells in the peripheral blood at which to start apheresis is a clinical decision. Although levels in the range from 50 to 100/μL or greater will reduce the number of apheresis procedures necessary to achieve a target goal of $CD34^+$ cells, each day's delay in initiating apheresis incurs the costs of additional cytokine administration and blood testing. In some patients who previously have undergone extensive treatment and who may show a slowly rising WBC count, multiple apheresis procedures may be necessary to achieve the target goal. No patient should undergo apheresis if the peripheral blood $CD34^+$ cell count is less than 5/μL (see Fig. 96-3). For patients with $CD34^+$ cell counts in the range from 10/μL to 20/μL, it is possible to process more blood per day using large-volume leukapheresis (LVL) techniques, thereby reducing the numbers of days the patients are required to return to the apheresis unit. Most patients mobilized with chemotherapy have a rising $CD34^+$ cell count in the peripheral blood, so starting apheresis the day after the patient has achieved a desirable $CD34^+$ level generally is feasible.[80]

The timing of apheresis after G-CSF mobilization differs from the timing after chemotherapy and cytokine mobilization. For both patients and healthy donors, the peak concentration of $CD34^+$ cells occurs on day 5 of G-CSF administration (after four daily doses).[57] Lower levels are present on day 4, and the concentration continues to fall after day 6, even if cytokine administration is continued and despite a possible continued rise in WBC count. Thus PBSC collection should be initiated on day 4 or 5 of G-CSF administration. The kinetics of $CD34^+$ cells in the peripheral blood for patients and donors mobilized with G-CSF alone are so reliable that monitoring of peripheral blood levels is not necessary unless there is concern that the patient has failed to mobilize cells and it is practical to obtain the cell count rapidly enough to initiate apheresis on the same day.

Physician Prescription for Apheresis and Peripheral Blood Stem Cell Processing

The attending physician should be aware of apheresis and laboratory procedures in order to maximize the value of PBSC components. The choices of venous access, anticoagulant(s), blood volume processed, target dose of $CD34^+$ cells, and cryopreservation volumes can be individualized. Apheresis unit staff may ask for guidance regarding pain medications, concurrent medications, and blood transfusions (although it is advisable to avoid transfusion during the apheresis procedure because of citrate or other reactions and because changes in the hematocrit may affect the efficiency of the collection). Adequate numbers of $CD34^+$ cells can be collected for more than one cycle of chemotherapy. It is important to communicate with the cryopreservation facility if PBSC components will be used to support more than one cycle of chemotherapy or if DMSO toxicity is of concern, in order to facilitate appropriate packaging of each product. Current cytometric techniques for quantification of $CD34^+$ cells require at least 1 hour of processing, so it may not be practical to prescribe the number of $CD34^+$ cells to be frozen in each bag. However, it is possible to divide the component into the number of bags equaling the number of anticipated infusions so that equal numbers of $CD34^+$ cells will be available for each.

Timing of Apheresis Using Plerixafor

Plerixafor administration results in a rapid mobilization of HSC into the peripheral blood with peak $CD34^+$ cell and CFU-GM concentrations occurring about 6 to 10 hours but with a wide range of activity extending to over 24 hours after administration of a dose of 240 mcg/kg.[81-83] The initial phase III studies demonstrating efficacy of this agent in patients failing to mobilize adequate cells with G-CSF alone required administration of plerixafor about 10 hours before apheresis, followed by daily administration of plerixafor until completion of collections. The broad duration of activity may allow alternate timing schedules and, conceivably, two apheresis procedures after one dose of plerixafor (particularly for patients with renal impairment[77]), although rigorous clinical studies addressing alternate timing schedules have not been performed.

Collection of PBSC by Apheresis

A number of apheresis devices are available for separating HSC from the peripheral blood. The devices may be classified as continuous flow (e.g., Fenwal CS3000, COBE Spectra, Fresenius AS104) or discontinuous flow (e.g., Haemonetics family of equipment). Discontinuous-flow devices have the advantage of requiring only a single venous access. Continuous-flow devices require two access lines for aspiration and return of blood, but they process much larger volumes of blood in a shorter period of time. All apheresis devices collect HSC. The choice of apheresis device used by the collection center depends primarily on the needs and experience of the center. Continuous-flow devices are more efficient in the collection of PBSC and are, accordingly, preferred over discontinuous-flow devices (see box on Physician Prescription for Apheresis and Peripheral Blood Stem Cell Processing).

Apheresis Technology

Apheresis technology is widely used for collection of platelets and other blood products from healthy donors and is considered to be without major risk to the donor. The important safety considerations for PBSC collection are the same as for platelet collection and include the venous access to be used for the procedure, the extracorporeal volume of blood during the procedure, and the solutions administered to the donor. Of note, however, PBSC collection for autologous transplantation involves patients with underlying medical conditions who may require considerable nursing care during the procedure. In a prospective evaluation of 2408 healthy unrelated volunteer donors, apheresis-associated adverse events were reported by 20% of female donors ($n = 964$) and 7% of male donors ($n = 1444$) on the first day of apheresis, falling to 10% and 4%, respectively, on the second day of collection (if performed).[63] Most (51%) of reported adverse events were related to citrate infusion. A smaller proportion of donors (22%) reported problems with venous access. Rare (1%-6% of events) adverse events included hypertension or hypotension, allergic reactions, fatigue, and syncope. The placement of a central venous catheter was required by 17% of female donors and 4% of male donors. Also, larger-volume and repetitive exchanges will result in platelet depletion.[62] The platelet count may reach its nadir several days after completion of the apheresis collections and discontinuation of G-CSF, and donors should be counseled in this regard.

Important caveats are that the donors in this analysis from the unrelated donor registry met strictly defined health criteria and were between 18 and 69 years of age. A higher probability of adverse events may be expected in patients and in donors of older (or younger) age. For example, in an older retrospective publication, Goldberg and colleagues studied the complications occurring during 554 PBSC collections from 75 consecutive patients.[84] Patient diagnoses and the mobilization treatment regimens were varied. All but one patient had subclavian or jugular venous system catheters placed for apheresis. A median of nine collections per patient were performed using a discontinuous-flow apheresis device. The most common problems were related to the venous catheters: 50% of patients developed at least one occlusion. Hypocalcemia occurred in 14.6% of patients and hypotension in 13.3%. Sixteen percent of patients experienced infectious complications during the PBSC collection period.

Staffing of the apheresis unit should be appropriate for the medical condition of the patients undergoing apheresis. Staffing must include nurses familiar with the care of the oncologic patient who may be recovering from marrow hypoplasia complicated by neutropenic fever requiring multiple medications and the care of a central venous catheter. Collection of PBSC by apheresis in the outpatient setting should be performed only after careful review of the medical support requirements for the individual patient or donor, and it should never be assumed to be a safer alternative for the donor or patient with a serious comorbid illness than marrow harvesting conducted in the intensive care setting of the operating room.

Venous Access

Adequate venous access is required for optimal apheresis technique. Continuous-flow apheresis devices require two-lumen access with a stable blood flow capacity generally greater than 20 mL/min. Single-lumen access may be used with discontinuous-flow apheresis devices, although at a much slower rate of blood processing. The great majority (≈95%) of adult male allogeneic PBSC donors have adequate arm veins for the procedure to be conducted "vein to vein," with female donors more likely to require alternate venous access.[63] Some donors, especially those with small veins and undergoing several daily procedures, may require placement of a temporary venous catheter. Venous access for the patient undergoing collection for autologous PBSC transplantation is much more heterogeneous. Vein-to-vein procedures can be performed, even on several consecutive days, with proper phlebotomy technique and postcollection care of the phlebotomy site. Most patients received previous chemotherapy or are proceeding directly to transplantation, conditions for which tunneled access is commonly placed. Ideally, this venous access should be appropriate both for the apheresis procedures and the subsequent transplant. Length, lumen size, and wall stiffness all affect the blood flow that can be achieved through a catheter. For this reason, the commonly used dual-lumen Hickman or Broviac catheters usually are unsuitable for apheresis, as are all subcutaneously placed ports. Most triple-lumen catheters are inadequate because of the small lumen size. If such access is already in place, consideration can be given to replacement with a shorter, stiffer tunneled catheter or to placement of a temporary percutaneous dialysis/apheresis catheter. The catheters designed for dialysis and apheresis have adequate wall thickness to prevent collapse during aspiration of blood as well as a tip design that decreases local recirculation of blood and the resulting decrease in apheresis efficiency. Catheters of 10 F or larger size are appropriate for adult patients. Pediatric patients, whose blood flow rates are considerably slower, may use catheter sizes of 5 to 7 F.[85]

Anticoagulation for PBSC Collection

Anticoagulants are added to the blood during apheresis to prevent clotting of the extracorporeal circuit and clumping of cells in the component. Citrate anticoagulants have a proven record of safety in the apheresis of healthy platelet donors. The major drawback is the risk for a symptomatic decrease in the level of ionized calcium ("citrate toxicity"), especially during processing of large volumes of blood. Citrate ions chelate calcium ions (and other divalent cations such as magnesium), making them unavailable for Ca^{2+}-dependent metabolic reactions. ACD-A contains 10.67 g of citrate per 500-mL volume in the form of trisodium citrate and citric acid. Citrate is diffused throughout the extravascular space, and this diffusion is the first defense against citrate toxicity. The body size and difference in muscle mass between men and women results in an increased risk for citrate toxicity for women in particular and smaller donors in general. Metabolism by liver, kidney, and muscle also reduces the concentration of citrate. Metabolism of citrate becomes more important during prolonged apheresis procedures such as LVL. The initial signs of citrate toxicity include circumoral or acral paresthesias and may progress to nausea, vomiting, loss of consciousness, tetany, and seizures. Because pediatric patients may not be able to relate the initial symptoms of the condition, citrate toxicity should be considered as the cause of any change of behavior, such as crying, during the apheresis procedure. Citrate toxicity is prevented by limiting the quantity of citrate infused either by decreasing the blood flow rate through the apheresis device or changing the blood-to-citrate ratio. The processing of blood of patients experiencing the initial symptoms of citrate toxicity should be temporarily halted until the symptoms abate and then resumed at a slower rate. The benefit of oral calcium supplements for these patients is not certain. Heparin can be used as a replacement for some or all of the citrate, although additional citrate is added to the component bag to prevent clumping of platelets. Some centers that use citrate anticoagulants also administer intermittent or continuous infusions of calcium gluconate during the procedure, especially if large volumes of blood are being processed. However, excessive calcium replacement can induce cardiac dysfunction.

Large-Volume Leukapheresis

The apheresis device has a uniform and fairly reproducible efficiency of collection. Thus for a consistent quantity of blood processed through the machine, the quantity of $CD34^+$ cells collected is directly related to the number present in the peripheral blood. Greater quantities of $CD34^+$ cells can be collected by increasing the number of these cells in the peripheral circulation or by increasing the volume of blood processed by the device. For patients with lower $CD34^+$ cell levels, multiple apheresis procedures will be required to achieve the target dose of $CD34^+$ cells needed for transplantation. An alternate approach

is to process the same total quantity of blood but in fewer, longer procedures. LVL is not standardly defined, but in general usage it refers to processing of more than two or three times the patient's blood volume. Typically, the quantity of blood processed is six or more times the patient's blood volume, often 25 to 36 L of blood. The advantage of LVL is that it reduces the number of days of cytokine administration and apheresis, with associated reduced costs of laboratory processing and testing. The apheresis techniques are the same as those used for processing of smaller volumes of blood, although blood flow rates may be increased to reduce the time required. The risks of LVL are the increased time required and the higher risk for citrate (or other anticoagulant) toxicity. Patients will also incur a proportional drop in platelet counts and may become profoundly thrombocytopenic.

Most reports of LVL describe the collection of more $CD34^+$ cells than are calculated to be present in the peripheral blood at the initiation of the apheresis procedure. Most likely, the ongoing release of cells from the marrow replaces those cells removed by apheresis (or returning to the marrow space).[86] Apheresis of $CD34^+$ cells is a three-compartment system consisting of the extracorporeal circuit of the apheresis device (including the collection bag), the peripheral blood, and the marrow. It is not obvious that the apheresis technique itself "mobilizes" $CD34^+$ cells, as suggested by some authors. This phenomenon, if it occurs, may be related to a decrease in divalent cations resulting from the citrate anticoagulant, possibly affecting cell adhesion forces.

Studies at the Fred Hutchinson Cancer Research Center demonstrated a continuous release of $CD34^+$ cells from the marrow (and, presumably, return to the marrow space).[86] Patients having higher levels of $CD34^+$ cells in the peripheral blood appeared to have a greater number of these cells circulating between the marrow and peripheral blood compartments (Table 96-5). In this model the apheresis device merely serves as a siphon, removing these cells from the blood as they are released from the marrow. If this description of $CD34^+$ cell kinetics is accurate, it may be possible to deplete these cells from the blood and marrow by prolonged processing, but probably only if limited numbers of them are present in the marrow compartment. Also, the model suggests that higher blood flow rates used to shorten the apheresis procedure may be counterproductive for patients with low $CD34^+$ cell levels in the blood because of the slower rate of release of $CD34^+$ cells in these patients.

Table 96-5 Replenishment of $CD34^+$ Cells During Large-Volume Leukapheresis*

	$CD34^+$ Cells				
UPN	*Blood (per μL)*	*Blood (Total)*	*Harvested (Total)*	*Released (Total)*	*Released (per min)*
10605	6.5	34.9	123.5	88.6	0.3
10698	15.6	603.3	1438.1	540.8	2.1
10849	30.7	109.7	211.1	62.6	0.3
10920	37.9	214.2	952.8	57.0	1.6
11128	66.1	280.6	1010.8	532.7	1.9

*Shown are numbers of $CD34^+$ cells in the peripheral blood or apheresis component for five patients with acute myelogenous leukemia or multiple myeloma undergoing large-volume leukapheresis after granulocyte colony-stimulating factor (G-CSF) or chemotherapy plus G-CSF mobilization treatment. Blood volumes processed were six times the calculated blood volume of the patient. Peripheral blood stem cell collection was performed on the COBE Spectra. The total number of $CD34^+$ cells in the blood (third column) was calculated from the level of $CD34^+$ cells in the blood and the estimated blood volume of the patient. The total number of $CD34^+$ cells released (fifth column) was calculated from the total number in the apheresis component and the number in the peripheral blood after collection minus the total number in the peripheral blood at the start of the collection procedure. All $CD34^+$ cell quantities (except blood levels reported per μL) are $\times 10^6$. Full data are given in Rowley SD, Yu J, Heimfeld S, et al: Trafficking of CD34+ cells into the peripheral circulation during collection of peripheral blood stem cells by apheresis. *Bone Marrow Transplant* 28:649, 2001.

Pediatric Donors and Patients

PBSC can be collected from pediatric patients, including infants. The special challenges of the pediatric patient arise from the fixed extracorporeal blood volume of the apheresis device, the need for venous catheters for blood access, and the management of a patient who may be unwilling or unable to rest quietly for the period of apheresis. It is especially important in management of the pediatric patient that timing of apheresis be optimal to minimize the number of procedures required to achieve the desired quantity of PBSC. Given these considerations, a number of centers have reported successful collection of PBSC from pediatric patients and donors.

Almost all pediatric patients undergo insertion of a venous catheter adequate for the flow rates expected, although older patients (>12 years) may tolerate vein-to-vein procedures. The whole blood flow rate for the pediatric patient is much reduced compared with that of adult patients, and catheters as small as 5 F may be adequate.

Appropriate management of fluid balance during the apheresis procedure is critical for the smaller patient. The volume of red blood cells contained in the extracorporeal circuit of continuous flow apheresis device could represent 30% to 50% of the red cell mass of a pediatric donor. Although discontinuous-flow devices are appealing because of the feasibility of performing apheresis with a single-lumen venous access, they may result in even higher extracorporeal volumes and should be avoided in the smallest patients. The obvious solution to this problem is to prime the apheresis device with ABO-compatible, irradiated red blood cells (leukocyte-depleted and cytomegalovirus-negative blood may also be desirable) when the blood in the extracorporeal circuit is expected to exceed 15% of the patient's blood volume. Packed red blood cell units can be diluted with saline or albumin (to reduce the loss of plasma protein that may occur). The red cells remaining in the extracorporeal circuit at the completion of the run need not be returned ("rinse-back"), although if performed slowly with monitoring of vital signs, rinse-back may actually increase the hematocrit after the procedure and otherwise reduce the need for red cell transfusions for these patients. For the intermediate-size pediatric patient (weight 25-50 kg), the apheresis device can be primed with a 5% albumin solution. This step will reduce the albumin loss that otherwise would occur. However, clotting proteins and other proteins not contained in this solution may decrease with repetitive apheresis.

The pediatric patient may not exhibit or relate the prodromal symptoms associated with citrate toxicity. Continuous calcium gluconate infusion can be incorporated into the procedure, or heparin can be added to the citrate anticoagulant solution or used as the sole anticoagulant. Sedation of the pediatric patient is usually not necessary, however, and hinders the ability to recognize the symptoms of citrate toxicity. (Some patients may require antihistamine premedication if the apheresis device is primed with red blood cells.) Centers routinely performing pediatric PBSC collection should design an environment conducive to the management of pediatric patients and develop support procedures that recognize the unique physical and cognitive features of pediatric patients.

The range in blood volumes for pediatric donors of differing ages is greater than the range for adult donors. Therefore most centers set a goal for volume processed based on the individual's blood volume instead of a set volume (e.g., two blood volumes versus 6 L of blood) for all patients. The pediatric patient may undergo LVL to achieve the target goal of HSC with fewer procedures. Blood flow rates for pediatric patients are slower than for adults to minimize the risk for citrate reaction. As with adults, the timing of apheresis can be optimized by monitoring the quantity of $CD34^+$ cells in the peripheral blood.

QUALITY CONTROL OF HSC PRODUCTS

Quantity of Bone Marrow Cells for Transplantation

Cell dose normally is used as a surrogate for the stem cell content of the marrow product because the definition of adequate HSC

products predated the availability of flow cytometric analysis of HSC content, and nucleated cell counting is the only quality control measure easily performed during the collection procedure. For autologous transplantation, cell doses of 1×10^8 nucleated cells per kilogram are adequate. Based on early reports that smaller quantities increased the risk for engraftment failure, most centers target 3×10^8 nucleated cells per kilogram of recipient weight for allogeneic transplantation. However, those early reports were of patients being treated for aplastic anemia, in which engraftment failure is a more common event. A review of unrelated donor transplantation found that recipients of higher cell doses experienced faster neutrophil and platelet engraftment, as well as better leukemia-free survival.[87] Pretreatment of the marrow donor with either GM-CSF or G-CSF may increase the number of myeloid progenitor cells harvested and decrease the period of posttransplant aplasia to that achievable by PBSC transplantation (see Table 96-2). $CD34^+$ cell dose now is being correlated with transplant outcomes—with more rapid engraftment kinetics, possibly lower transplant-related mortality, and better overall survival, for example, in recipients of allogeneic bone marrow products containing higher quantities of $CD34^+$ cells.[88] This assay should be a routine component of bone marrow product quality control.[88]

Definition of Adequate PBSC Component(s)

The quantity of $CD34^+$ cells in a PBSC component varies greatly and is dependent on the number in the peripheral blood at the time of apheresis, the volume of blood processed, and the efficiency of the apheresis device. Therefore any definition of an adequate component cannot include a set number of $CD34^+$ cells to be contained in any single apheresis component. Instead, one or more components will be collected to meet the appropriate dose of these cells for transplantation. The dose of $CD34^+$ cells required for infusion depends on the intended treatment regimen. For marrow-ablative regimens, increasingly higher $CD34^+$ doses results in greater likelihood of rapid engraftment (Figs. 96-1 and 96-2).[89] Lower doses of $CD34^+$ cells appear satisfactory for nonablative regimens.

Patients who receive a dose of $CD34^+$ cells above a certain threshold will engraft. At lower doses of $CD34^+$ cells, considerable heterogeneity occurs in engraftment speed, especially for platelet engraftment. Why this heterogeneity exists is not known, but it may reflect a weakness in the correlation between $CD34^+$ cells and the cells responsible for engraftment, a greater heterogeneity of $CD34^+$ subsets collected, or perhaps, simply a greater degree of error in the measurement of $CD34^+$ cells at the lower cell concentrations. As the dose of $CD34^+$ cells increases, the engraftment kinetics becomes both more rapid and more consistent for the population studied.[89]

Subset analysis of $CD34^+$ cells may improve the accuracy of predicting neutrophil and platelet engraftment kinetics but does not appear to predict engraftment failure enough to be of clinical utility. Pecora and colleagues reported that the quantity of $CD34^+CD33^-$ cells infused was identified as an independent factor predictive of engraftment kinetics.[90] Dercksen and colleagues reported better correlation between the number of $CD34^+CD33^-$ cells and time to granulocyte engraftment and between the number of $CD34^+CD41^+$ cells and time to platelet engraftment than found with the overall number of $CD34^+$ cells.[91] Coexpression of adhesion molecules is also predictive of hematopoietic recovery, with the same pathways important for both mobilization and homing of HSC.[92] Given the limited range in recovery times when adequate numbers of $CD34^+$ cells are collected and infused, however, this additional information is currently of limited clinical value.

$CD34^+$ cell dose is also predictive of outcome of allogeneic PBSC (and marrow) transplantation.[88] Higher $CD34^+$ cell doses result in better neutrophil and platelet engraftments after either related or unrelated donor transplantation and may correlate with better survival after bone marrow transplantation, but may also be associated with the development of more chronic GVHD.

Management of Donor-Recipient Red Blood Cell Incompatibility

Transplantation of hematopoietic progenitor cells from ABO (or other red cell antigen) incompatible donors occurs in ≈30% of patients undergoing related or unrelated donor allogeneic HSC transplantation.[20] The immunohematologic consequences of red cell incompatible transplantation include delayed red blood cell recovery, pure red cell aplasia, and delayed hemolysis from viable lymphocytes carried in the graft ("passenger lymphocytes"). The risks for these reactions, which may be abrupt in onset and fatal, can be minimized with appropriate graft modifications to remove incompatible red cells and plasma, attention to the pretransplant conditioning and posttransplant immunosuppressive regimens, and prescription of proper blood product support.[20]

Red cell incompatibility is classified into two categories: one in which the recipient has antibodies directed against donor red cells with the potential for acute hemolysis upon infusion of the component (major incompatibility) and one in which the donor has antibodies against the recipient. Although the latter rarely causes difficulty during infusion of incompatible plasma, B lymphocytes carried in the component can form isoagglutinins, resulting in a delayed transfusion reaction 7 to 12 days after transplantation. Although PBSC components have much greater numbers of B cells compared with other HSC products, it is not clear that delayed-type transfusion reactions will be more likely or of greater severity in PBSC recipients. The risk for immediate hemolysis resulting from infusion of incompatible donor red cells is minimized by minimizing the quantity of red cells infused. There is no "safe" quantity of red cells below which the recipient will not experience an immediate transfusion reaction, but fatal reactions appear more likely for recipients of ABO incompatible blood products containing more than 50 mL of red cells.[20] PBSC products collected by apheresis contain only a few milliliters of red blood cells. Bone marrow products can be similarly depleted by processing using an apheresis device. UCB products can be depleted of red cells before cryopreservation to reduce the risk from infusion of ABO incompatible products and to reduce the space requirements for storage.

Tumor Cell Contamination

The probability that tumor cell contamination of HSC product could contribute to relapse was demonstrated by Brenner and colleagues in studies involving the autologous transplantation of genetically marked marrow cells,[93] as well as in individual case reports describing the transmission of malignancy to allogeneic recipients from donors with occult disease at time of harvesting.[25,26] Sensitive immunocytostaining techniques, clonal assays, flow cytometric analysis, and polymerase chain reaction amplification of malignant genetic material detect tumor cells in the autologous PBSC components of many patients with a variety of malignancies.[94] In general, the incidence of contamination (number of patients with positive components) and the level of contamination (number of tumor cells per number of normal cells) is much less for PBSC than for marrow products.

The presence of tumor cells at the time of collection or persisting after ex vivo processing may correlate with the extent of systemic disease or the chemotherapy-sensitivity of disease at the time of cell collection. Whether patients transplanted with autologous PBSC have a lower relapse rate compared with patients receiving bone marrow is not well defined, and appropriate phase III studies of this question will be difficult to design and enroll with patients in light of the other well-defined advantages of PBSC transplantation. In a retrospective study, Sharp and colleagues demonstrated similar probabilities of relapse-free survival in recipients of PBSC or marrow components if the components were free of lymphoma cells.[95] In that study, patients with marrow involvement by lymphoma were assigned to transplantation with PBSC. The authors concluded that PBSC transplantation is a sensible approach to the patient with overt marrow involvement. However, Brugger and colleagues demonstrated

that patients with breast cancer involvement of the marrow at the time of chemotherapy mobilization were likely to mobilize tumor cells into the blood. The most disturbing finding of this study is that the tumor cells were detected in the peripheral blood at the same time as $CD34^+$ cells.[96] Similarly, Pecora and colleagues found a relationship between the ability to detect tumors in PBSC components and in bone marrow samples, but they also found a higher incidence of positive PBSC components for patients who required greater numbers of apheresis procedures to achieve the target dose of $CD34^+$ cells.[97] Investigators at The Johns Hopkins Oncology Center found no difference in the incidence of tumor contamination of PBSC components between patients treated with chemotherapy and cytokines and those treated with cytokines alone.[98] Ex vivo purging of tumor cells from PBPC products has not been shown to reduce the risk for relapse after autologous transplantation, either because the techniques are not adequate in depleting minimal residual disease or because patients relapse primarily from endogenous disease surviving the pretransplant conditioning regimen. Patients with marrow involvement may benefit from several cycles of debulking (in vivo purging) chemotherapy before collection of HSC, with the caveat that extensive chemotherapy will also decrease the subsequent yield of PBSC. Tumor cells in the HSC inoculum likely will not benefit the patient, but until further data demonstrating a deleterious effect on transplant outcomes are available, it is advisable that reports of tumor contamination in the collections for individual patients be interpreted with caution.

Microbial Contamination of Hematopoietic Stem Cell Components

Bacterial culture is an essential quality control component in HSC collection and transplantation used to identify errors and breakdowns in manufacturing technique. Skin flora are the bacteria usually isolated, and infusion of culture-positive HSC products is generally without clinical sequelae, although serious infections have occurred after infusion of HSC products contaminated during processing.[38] Culture-positive products need not be automatically destroyed. Any decision regarding the disposition of a culture-positive HSC product must be made by the patient's transplant physician after considering the type of contamination, the anticipated risks from use of the component, and the ability to replace the culture-positive product(s) in a timely manner.

The incidence of culture-positive PBSC components is considerably less than that for marrow. The actual incidence of contamination for all HSC products is likely several times higher than reported, however, because most laboratories will culture only a very small volume of product (≈1 mL). In a retrospective review of 2935 HSC products processed and transplanted at one center, positive microbial products were reported for 1.3% of bone marrow products, 0.7% of PBSC products, and 2.0% of UCB products.[38] Coagulase-negative *Staphylococcus* and *Bacillus* species accounted for 23 of the 38 positive cultures, but *Escherichia coli, Klebsiella pneumonia,* and *Pseudomonas cepacia* were cultured from one product each. The recipient of the *Pseudomonas*-contaminated product subsequently died of complications of *Pseudomonas* sepsis, but no adverse sequelae could be documented for any of the other 34 recipients of culture-positive products. The highest rate of contamination occurred in the UCB products collected for related donor transplantation (5 of 18, 27.8%), likely a reflection of the collection techniques in place at the time, and illustrating the need for strict quality control in the collection and processing of HSC products.

Quantitation of $CD34^+$ Cells

Quantification of CD34 antigen-positive cells by flow cytometry has become the standard of care for management of the PBSC donor because it provides a rapid and clinically relevant assessment of HSC content in the peripheral blood or in the PBSC product. This antigen is found on HSCs (including a variety of subpopulations) and limited populations of other blood cells[99] and can be identified using a variety of commercially available antibodies. If antibodies directly conjugated with dyes are used, the technique requires only about 1 hour of preparation time. Cell viability using propidium iodide (PI) or 7-aminoactinomycin D (7-AAD) exclusion can simultaneously be determined if the cells are analyzed while still fresh, or the cells can be fixed after staining for analysis at a later date. Other antibodies can be added for analysis of CD34 subsets if desired (and if the flow cytometer has proper detectors to detect the different emission wavelengths of the fluorochromes used). A strong correlation exists between the numbers of $CD34^+$ cells and CFU-GM in the sample but with ratios of about 5:1 to 20:1.[100] Thus CD34 analysis will provide data similar to that obtainable with cell cultures, except that the latter demonstrates the functional viability of the progenitor cells. Mobilized PBPC products contain a heterogeneous mixture of cells including $CD34^+$ cells belonging to different cell subsets. Subset analysis of $CD34^+$ cells will provide additional information regarding early and sustained engraftment after autologous PBPC transplantation but does not appear to be clinically useful for the patient who easily meets the PBSC collection goal.

The major difficulty with analysis of $CD34^+$ cells is the low frequency of these cells. Clinical decisions to initiate apheresis are being made for $CD34^+$ cell levels as low as 10/μL. This may represent a cell frequency that is 0.01% or less of the nucleated cells in the specimen. This enumeration is possible because of multidimensional measurements obtained by flow cytometry. Most cytometers can measure at least five characteristics of each cell, including size, granularity, and the presence of up to three different fluorochromes. Thus the cells of interest can be separated in five-dimensional space, achieving discrimination of cells as rare as 1:10,000. The difficulties arise from developing an adequate technique that makes optimal use of the cytometer to measure these rare cells. Sources of errors include (a) sampling of the HSC product, (b) cell counting, (c) cytometer calibration and operation, (d) choice of antibody and fluorochrome, (e) lysis technique, and (f) gating strategy. Moreover, cytometry provides a proportion of cells, which must be multiplied by the cell count to obtain an absolute number. The steps involved in preparing a specimen for cytometry may alter the proportion of cells in the sample, and this error will be translated into an error in the absolute number. Clinically, this imprecision may explain some of the range in engraftment kinetics observed for patients receiving low doses of $CD34^+$ cells.

Progenitor Cell Cultures

Hematopoietic progenitor cells committed to granulocytic (CFU-GM), erythroid (burst-forming unit-erythroid [BFU-E]), or mixed granulocytic and erythroid (CFU-granulocyte, erythrocyte, megakaryocyte, macrophage; CFU-Mix) lineages can be identified using a variety of culture techniques. These techniques require expertise and equipment not available in many clinical laboratories. Other than availability of equipment and expertise, the major limitation is that progenitor cell assays require 10 to 14 days of culture before the results are available. Thus progenitor cell cultures cannot be used in the day-to-day management of the PBSC donor or the immediate quality control of bone marrow products. As with quantitation of $CD34^+$ cells, the lack of a standard culture technique adopted by all laboratories complicates comparisons between laboratories of progenitor cell quantities harvested and infused. The clinical relevance of the culture technique to the transplant population must be determined if the data obtained are to be used in the management of individual patients.

Unlike other measures of component quality, progenitor cell cultures demonstrate the functional potential of the cells. Progenitor cell cultures are the only currently available relevant assay of HSC viability other than actual engraftment of the recipient and should be available at the HSC processing facility for use in quality control or if questions about the viability of a particular component are raised.

CHAPTER 97

PRECLINICAL PROCESS OF CELL-BASED THERAPIES

Robert Lindblad, Deborah Wood, Traci Heath Mondoro, and Leslie E. Silberstein

The use of cells as more than replacement therapy has become a reality over the course of the past several years. While basic and clinical scientists are developing many new and promising strategies to improve immune reconstitution and transplant outcome, they are dependent on many others to implement these new therapies. Ultimately, implementation of procedures that were successful in the laboratory can be expensive and difficult to scale up to a process that will produce the required dosage with consistent quality for clinical trials. To cope with these issues, many institutions have established specialized cell processing centers; however, a specialized cell processing laboratory and specially trained laboratory staff do not resolve all of the problems associated with scaling a new procedure for a clinical trial. In some cases, equivalent reagents and processes suitable for clinical work are not available.

In addition to the technical challenges of producing clinical grade cells, all of this work must be performed under the Investigational New Drug (IND) process through the U.S. Food and Drug Administration (FDA). The use of any investigational therapy in humans requires an IND, and even if the cellular therapy has been approved, a new IND must be filed if the agent is being tested in new populations or a situation in which the risks are unknown. Novel cell therapies are more than minimally manipulated from their original source, so the FDA must review the procurement, storage, processing, and other manufacturing details as well as the clinical trial design. A study that is not likely to yield interpretable results is considered an unethical study because it places participants at risk without the prospect of either direct or generalizable benefit.

As the field of cellular therapy moved beyond transfusion of blood components and bone marrow transplantation, it became apparent that the preparation of the cellular product was becoming a science unto itself. The isolation and identification of the desired cell population could take months, and the optimization of this process could take years. This did not include the development and validation of potency assays. All of this work is expensive and labor intensive and requires staff qualified to perform at the highest technical level. Even though these tasks are vital to the production process, they are not hypothesis driven, so this type of work does not meet the requirements for National Institutes of Health (NIH) research project grants. One of the review criteria for NIH grant applications and contract proposals is innovation. Work required to validate a scale-up procedure and potency assays is not considered innovative and is not eligible for discovery research that is typically funded through NIH grants. Many investigators perform this translational work by piecing together funding from institutional or philanthropic sources. The National Heart, Lung, and Blood Institute (NHLBI) sponsors the Production Assistance for Cellular Therapies (PACT) program, which provides translational services for cellular therapies or the manufacture of clinical grade cells. The National Institute of Biomedical Imaging and Bioengineering (NIBIB) funds hypothesis-driven research related to technologies, and some investigators have been able to utilize services provided by NIH Clinical and Translational Sciences Awards (CTSA) programs. Regardless of the source of funding, this chapter provides general information about requirements during the preclinical phase of the development of a cellular therapy before it is tested for safety in a clinical trial. Critical elements involved in the stages of cell therapy product development are outlined in Fig. 97-1.

OVERVIEW OF THE CELL THERAPY PRODUCT

Novel cell-based therapy offers great potential for treating a number of currently untreatable disorders and diseases, including immune reconstitution, tissue repair and regeneration, and metabolic support. Cell-based therapies can be derived from a variety of human autologous, allogeneic or xenogeneic tissue sources such as blood, bone marrow, adipose, umbilical cord blood, fetal, embryonic stem cell lines, and induced pluripotent cells. Cellular engineering techniques such as selection, depletion, expansion, and genetic modification can be applied to alter or modify a cell to achieve a desired therapeutic effect. With these novel cell therapies; however, come development, manufacturing, characterization, and testing challenges in generating a safe and effective cell therapy product.

Challenges for Cell Therapy Product and Manufacturing Development

Current good manufacturing practices (cGMP) govern manufacturing processes to ensure consistent manufacture of safe, pure, and potent products.[1] Current good tissue practices (cGTP) govern the methods used in and the facilities used for the manufacture of human cells, tissues, and cellular and tissue-based products (HCT/Ps). cGTPs focus on the prevention of the introduction, transmission, and spread of communicable diseases and other adverse events while preserving product function and integrity.[2]

Biologic Variability

Living biologic products present unique challenges. Cells need to be alive in order to function. With cell-based therapy, inherent patient-to-patient biologic variability and cellular heterogeneity are issues. Cell therapy products are derived from tissue sources that contain multiple cell types. In addition to known "active components," there are known and unknown cell subpopulations that may be considered "contaminants" or "inactive components" or be critical to the biologic function of the product. Evolving characterization and rigorous process control are critical to counter the intrinsic heterogeneity and variability.[3]

Characterization

Cell therapy products are difficult to fully characterize. Critical decisions need to be in the product development stage, and the establishment of a characterization profile should occur early in the process. Successful product development demonstrates that the cell therapy

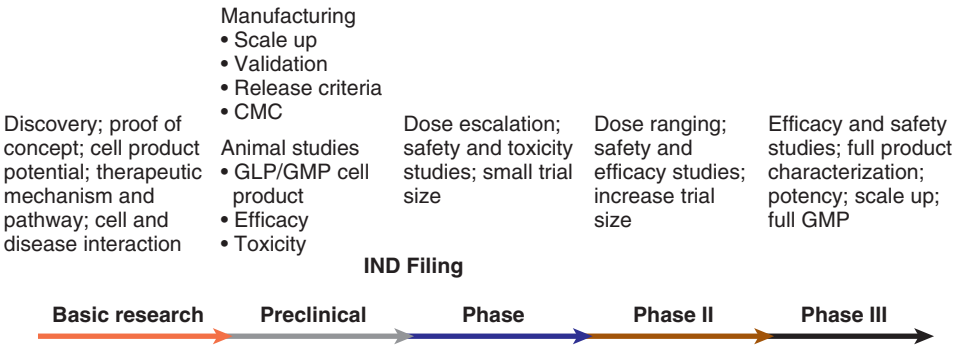

Figure 97-1 CELL THERAPY PRODUCT DEVELOPMENT. *CMC,* Chemistry, manufacturing, and controls; *GLP,* good laboratory practices; *GMP,* good manufacturing practices; *IND,* Investigational New Drug.

product is safe, pure, potent, effective, and stable. Of these five elements, developing a potency assay for cell therapy products is most challenging. Potency measures the product's relevant biologic function. Biologic products are inherently complex, variable, and often heterogeneous, with complex or poorly defined mechanisms of action(s). Despite complex cell engineering processes, the final product may contain both therapeutic and nontherapeutic cells. It is difficult to ascertain if the combination of "active" and "inactive" components contributes to biologic function. Because cells and cell lines are genetically diverse, they may behave differently during manufacturing than they did under experimental conditions. Cell characterization testing, particularly with respect to potency, will evolve and change significantly during preclinical and clinical product development.[4]

Raw Materials

Many types of raw materials are used in cell therapy manufacturing. Such materials include culture media, sera, growth factors, cytokines and "feeder cells" that are used to support cell growth. They may be simple or complex and may remain in the final therapeutic product as active substances or as excipients. They may also be used in the manufacturing process as ancillary products. Raw materials can affect the cell product characteristics. They may be viable, functional, or biologic materials, and all must be qualified. A qualification program for raw materials needs to be implemented to ensure the consistency and quality of raw materials and be designed to address identification and selection of the material, suitability of materials for use in manufacturing, characterization of materials, justification for use of animal-derived materials (e.g., fetal bovine serum), and quality assurance for all materials.[5]

Adventitious Agents

Adventitious agents or contamination may originate from the source (e.g., infected animals or tissues), during cell culture manipulation (e.g., repeated passages and manipulation in the laboratory), or by using contaminated biologic reagents. Unidentified diseases may exist in the use of xenogeneic cells. The range of infectious agents that produce little or no effect in animals may have severe consequences in humans. With xenogeneic materials, rigorous qualification of source animals and primary cell substrates is critical. Also, complex cell engineering procedures may extend over months and can result in an increased risk of contamination and other adverse effects. Quality control of the manufacturing process as well as the final product is necessary. Poor control of production processes can lead to the introduction of adventitious agents or other contaminants or to inadvertent changes in the properties or stability of the biologic product that may not be detectable in final product testing.[6]

Aseptic Processing

Living functional cells are the product, so terminal sterilization is not an option. Therefore, aseptic processing is required. The risk of delivering a contaminated product is increased because of the inability to sterilize the product and that product administration may occur before final sterility testing has been completed. This is why testing for contamination and cross-contamination are implemented as safety measures during the multistep cell processing procedure. The nature of the starting material and processes that involve open or closed manipulations determine the level of a controlled environment to be implemented.

Target Cell Population

Cells of therapeutic interest are often found in small numbers. An important step involves initial isolation or enrichment of a cell population of interest from the tissue source. Several commercial systems are already in use and include the CliniMACs (Miltenyi Biotec), the Sepax (BioSafe SA), and Elutra (CaridianBCT, Inc.) systems. Cell culturing processes are cell type specific. Cells such as T cells can be grown in nonadherent suspension culture where large-scale bioreactors such as bag-based and traditional stirred-tank vessels are used. This culturing system requires a small surface area and can produce a high cell yield. There is a growing interest in ex vivo expansion of adherent cells for a variety of clinical applications. Mesenchymal stromal cells are grown adherently on tissue culture–treated surfaces but require a large surface area to produce on a large scale. Miltenyi culture bags offer a closed system process along with the CLINIcell (MABio). Multilayered flasks have been developed (CellCube and CellSTACK, Corning, Inc.) to address surface area and bioreactors, and microcarrier-based culturing systems are currently in development (SoloHill Engineering, Inc., Ann Arbor, MI).[7]

Autologous Versus Allogeneic Products

Given their unique donor specificity, autologous products are attractive because of their decreased risk of immunologic reactions, bioincompatibility, and communicable disease transmission. However, they are inherently more limited and more variable because of individual patient characteristics and disease state. Use of allogeneic donors is associated with a greater risk than autologous donation because of the risk of infectious disease transmission from the donor to the recipient, the overall risk of an immune response, and donor-to-donor variability. Allogeneic cells have the potential to treat hundreds of patients from a single manufactured lot of cells and can be an "off-the-shelf" product.

Methods used in the production of cell products for clinical therapies depend on the nature of the final product and their targeted

population. Autologous products are patient specific and are manufactured using a "scaled out" approach. Cells are manufactured in small volume batches, and each patient constitutes his or her own "lot" of product. Allogeneic product manufacturing can use a "scaled up" approach with a bulk manufacturing strategy to produce larger volume batches.

In summary, cell therapy products are being used in a variety of therapeutic indications. However, living biologics carry elements of risk. Rigid control processes to minimize risk need to be implemented. Characterization, although a predictor of efficacy, is not a predictor of safety or quality. Because full characterization is unlikely, it is imperative that manufacturing and aseptic processes be controlled and consistent to produce a safe reliable product. If manufacturing changes, as is often the case, essentially a new product is created and recharacterization, and repeat testing will be required to assess comparability of those changes.

THE REGULATION OF CELL THERAPY PRODUCTS: THE CENTER FOR BIOLOGICS EVALUATION AND RESEARCH

The Center for Biologics Evaluation and Research (CBER) currently regulates cell therapy products considered as HCT/Ps under two sections of the Public Health Service (PHS) Act.[8,9] Section 361 includes products that require no premarket approval and are consistent with products defined in 21 CFR 1271.10,[10] that is, minimally manipulated, homologous use, not a combination product, and either has no cellular or systemic effect or, if it is active on a cellular or systemic basis, is used in an autologous setting, in an allogeneic setting in first- or second-degree blood relatives, or is for reproductive use. Section 351 of the PHS Act[10,11] includes products that require premarket approval, that is, require data with clinical investigations to be collected for FDA review under an IND application and do not meet the definition of exempt products described above for Section 361 products. Cell therapies that also have a device or scaffold associated with them can be regulated by the Center for Devices and Radiological Health (CDRH) as a consultant to CBER or as the lead center if the scaffold is the primary mode of action. Table 97-1 summarizes regulation of HCT/Ps as 351 and 361 products.

Table 97-1 Determination of 351 and 361 Classification of Human Cells, Tissues, and Cellular and Tissue-Based Products

HCT/Ps Regulated Under 351 of the PHS Act	HCT/Ps Regulated Under 361 of the PHS Act
Require IND premarket approval; do not meet the definition of exempt products described above 361 products; 21CFR 1271	No premarket approval requirement
More than minimally manipulated	• Minimally manipulated, and
Not intended for homologous use	• For homologous use, and
Associated with a device or scaffold*	• Not a combination product, *and* either
Cellular or systemic effect or dependent of metabolic activity of the cells for its primary function	• has no cellular or systemic effect *or* • if it is active on a cellular or systemic basis is used in an autologous setting or in an allogeneic setting in first or second-degree blood relatives or is for reproductive use

HCT/Ps, Human cells, tissues, and cellular and tissue-based products; *IND,* Investigational New Drug; *PHS,* Public Health Service.
*Cell therapies that also have a device or scaffold associated with them can be regulated by the Center for Devices and Radiological Health as a consultant to Center for Biologic Evaluation and Research or as the lead center if the scaffold is the primary mode of action.

THE INVESTIGATIONAL NEW DRUG PROCESS

Presented here is a summary of the basic procedures to file an IND with the FDA. The regulatory pathway to conduct a clinical trial using a cell therapy product involves an IND the majority of the time.

Investigational New Drug Sponsor and Investigator

The *sponsor* of an IND trial is the individual or organization that takes legal responsibility for and initiates the clinical investigation. This may be an individual, an academic institution, the government (the NIH), or a pharmaceutical company. In contrast, the *investigator* is the individual who actually conducts the clinical trial and under whose direction the investigational product is administered. In many small cell therapy clinical trials, the sponsor may in fact also be the investigator so that the trial is conducted under a single individual who is designated as a *sponsor/investigator*.[12]

Requesting a Meeting

Product regulatory development almost always begins with meetings between the sponsor and FDA. Even with the availability of various Guidance Documents, sponsors are rarely in a position to submit a successful IND application with a cellular therapeutic product without direct FDA interactions in order to agree on submission details. The agency has designated meeting types to create a consistent level of support for products under development.

Type A meetings are used to discuss products stalled in the development pathway and products that have been placed on clinical hold after a clinical trial is already underway. Type C meetings are any other meetings not covered under type A or B.[13,14]

Type B meetings (the most common) include several specified time points in the development of a product. These include a pre-IND, end of phase I, end of phase II/pre–phase III, pre–Biological License Application (BLA), Product License Application (PLA), Establishment License Application (ELA), and New Drug Application (NDA) meetings. Under the performance goals set for the FDA, type A meetings should occur within 30 calendar days from receiving the request, type B meetings within 60 days, and type C meetings within 75 days. Information should be submitted to the agency 14 days before the meeting for type A meetings and 30 days before the meeting for type B and C meetings.[14]

Pre–Investigational New Drug Meeting

For cell therapy products, the most critical meeting is the pre-IND meeting. The general format of a pre-IND package that the sponsor sends to FDA 30 days before the meeting will include the proposed clinical protocol and consent, preclinical information, any existing clinical information, a manufacturing section, and hard copies of pertinent references. The closer the pre-IND package parallels the content of the anticipated IND, the more likely a complete review can take place and key questions can be addressed before submitting the IND itself. A list of questions that the sponsor would like the FDA to address and focus the discussion is critical to the success of the meeting. The FDA will specifically address these questions and provide a formal response as part of the meeting minutes. These questions should include issues related to the preclinical testing data; chemistry, manufacturing, and controls (CMC) information; and the clinical protocol.

The sponsor, principal investigator, individual responsible for the preclinical work, and cell manufacturer should attend the pre-IND meeting. The FDA will be represented by reviewers to match these

areas. After the pre-IND meeting, the FDA reviewers in general make themselves available for further discussion and clarification or can review a new manufacturing technique or a preclinical study to ensure that the sponsor and the FDA are in agreement regarding the next steps. This process is a collaborative process with the goal of moving the development into the clinical arena as quickly and as safely as possible. Engaging the FDA early on in the IND submission process is recommended to facilitate the IND's overall success. Within CBER, pre-Pre IND meetings are available that are nonbinding, informal scientific discussions between CBER nonclinical (pharmacology/toxicology and manufacturing) reviewers and the sponsor to initiate dialogue at an early stage in the process. This structure reflects CBER's willingness to engage the cell therapy community early in the development process and helps avoid delays caused by a lack of communication.

Investigational New Drug Submission

The submission of the IND will follow the pre-IND meeting must fully address the issues raised at the pre-IND meeting in order to move forward. When the IND is submitted, the FDA has 30 days to respond. The IND may proceed unless the FDA reviewers provide comments or place the IND on hold within that 30-day time limit. Typically, the FDA will have comments and will contact the IND sponsor before the 30-day deadline. The IND submission is organized in a similar fashion to the pre-IND package noted above. Several key sections in the IND are the clinical protocol with appropriate eligibility, end points, stopping rules and dosing justification, the CMC section, and the preclinical section.[12]

Chemistry, Manufacturing, and Control Section

Unlike chemical manufacturers that may produce a massive lot to treat multiple individuals, cell therapies are usually a single lot to treat a single individual. The CMC section of a cellular therapy IND is crucial to the success of an IND submission.[15] From the regulations in 21 CFR 312.23,[16] sufficient information is required to assure the proper identification, safety, quality, and purity of the cell product. The *drug substance* is the starting material(s), including the procurement, process description, and test methods used to determine identity, strength, quality, and purity. The *drug product* is the end product, and its composition, manufacturing methods and packaging, and stability data should be included. Components used in the manufacturing of the IND; active, inactive compendial, and noncompendial excipients should be listed. If available, Certificates of Analysis for reagents not FDA approved should be submitted. The IND/GMP Sliding Scale was developed with the recognition that manufacturing under cGMP is a challenge for early stage cell therapy research. Perceived deviations from standard cGMP can be acceptable with scientific justification and an alternative approach proposed. FDA will not direct the development of the product but will respond to the data-driven suggestions put forward by the sponsor in an IND application.

The format of the information that is included in the CMC section of an IND is described in (CFR 312. 23).[16] Typical problems encountered with submission of CMC sections include:

- Poor organization and key elements missing from the submission.
- Incomplete descriptions of materials and reagents used in the manufacturing process
- Insufficient facility information
- Insufficient details regarding release criteria and tests employed.
- Insufficient standard operating procedures (SOPs)

Pharmacology/Toxicology Section

The pharmacology/toxicology section must support the planned clinical trial. Pharmacology information should describe the pharmacologic effects and mechanism of action in the animal model and provide information on the absorption, distribution, metabolism, and excretion of the product. In cellular therapies, much of this information is not readily measurable. An attempt to organize the preclinical data to address these areas should be made. If this information is not known, it should be stated. Toxicology studies, on the other hand, are critical to the initiation of clinical trials in humans.

Preclinical animal studies in general will be conducted in two species under good laboratory practices (GLP) conditions, including a developed protocol and complete data record keeping. An adequate number of animals, typically of both sexes, and adequate sampling time points are required. The appropriate species include a proof of concept relevant animal model of the appropriate disease or injury and a healthy animal toxicology model. One study must include the same route of administration, the same cell manufacturing technique, and the same product as will be proposed in the clinical study. Deviations from this ideal should be clearly explained and justified scientifically. The pre-pre–IND meeting is the time to decide the acceptable animal models to conduct these studies before embarking on time-consuming, expensive pathways that do not adequately answer the questions to advance the development process.

Cross-Referencing

The FDA permits one IND to cross-reference information that is already on file at the agency. Written authorization must be obtained from the sponsor of the submission that is being cross-referenced. Specific details, including the submission and volume number and the heading and page numbers, should be provided to identify what material is being cross-referenced. This allows FDA reviewers to quickly locate the referenced materials, facilitating the review process.

An Investigational New Drug Hold

After the IND is filed, FDA has 30 days to respond with comments before the IND automatically becomes active. The FDA applies a clinical hold to stop the clinical investigation from proceeding until identified issues are adequately addressed.[17] For new INDs, this represents a failure of the pre-IND process. If the sponsor in the pre-IND meeting presents sufficient detail and asks appropriate questions, then potential hold issues will be addressed before the IND submission. The FDA will put a clinical trial on hold for predefined reasons that include:

- Exposure to unreasonable risk for significant illness or injury
- Clinical investigators are not qualified
- Investigator brochure is misleading, erroneous, or incomplete
- IND does not contain sufficient information to assess risk
- Gender exclusion for a condition that occurs in both men and women

In practice, a clinical hold on cell therapy INDs is applied for several reasons, which include:

- The clinical trial does not provide adequate safety protection, which includes appropriate dosing based on the preliminary clinical or preclinical data, appropriate dose escalation, and appropriate stopping rules for the trial.
- The pre-clinical data do not support the clinical trial based on product manufacturing or route of delivery.
- The manufacturing section has inadequate characterization of the product, inadequate controls over manufacturing, and insufficient details.

These issues should all be addressed in the pre-IND process.

Investigational New Drug Maintenance

When an IND becomes active, future communication with the FDA outside of specific meeting requests occur through the submission of IND amendments. Each submission is sequentially numbered and adds to the overall content of the IND. Amendments are submitted to the IND on a rolling basis and include protocol revisions, expedited safety reports, changes to the manufacturing technique or to the facility, key personnel changes, and any other significant changes to the clinical or manufacturing portions of the IND. Additionally, each IND sponsor is required to submit an annual report. In some cases, the FDA may require more frequent progress reports. Each annual progress report is an opportunity to submit other details regarding the IND that were not submitted during the year. The annual report is due within 60 days of the anniversary date of the IND's becoming active.

When Is a Cell Therapy Product Ready to be Tested in a Clinical Trial?

The ultimate test of the cellular therapy is its performance in human trials. This is the last step of an incredibly complex journey. The cell population has been identified along with a manufacturing method and assays to characterize the consistency and key properties of the product. The manufactured product has been tested in animal models for both proof of concept data, including the route of administration, dosing schemes, and toxicology. The best way to make the transition from animals to humans smoothly is, if possible, to continue working with the same cell processing facility and staff that have been preparing the product throughout the preclinical studies. Good communication among the investigator, the cell processing staff, and the FDA is key for the success of the clinical trial. When this occurs, then it is easier to solve inevitable operational difficulties, attribute adverse events, and solve recruitment problems that may occur during the course of the trial.

Trial Design Considerations

The initial studies are safety based, typically at a single center, exposing few humans to the new therapy and carefully monitoring for adverse effects. As development continues, the clinical trial design can be broken down into two broad areas, scientific and operational. The scientific area includes the clinical questions to be answered and the statistical methods used to answer them. The investigator and the cell processing staff should meet early with statistical staff to determine how to phrase the clinical questions so that they can be answered with the proper end points. If a surrogate end point is proposed, this should be discussed with FDA staff. The method of end point measurement must be determined. Is there an existing validated assay to measure the end point? Is the assay commercially available, and is it FDA approved for clinical use or is it a "research-based" assay? The statisticians will calculate the appropriate sample size that is required to answer the questions with sufficient statistical power. After the sample size has been derived, the investigators must determine if the trial can be conducted at one center or if a multicenter study is needed.

Operational Issues

These are addressed using experience gained from prior clinical trials or may need to be solved through pilot studies or "dry runs" by the manufacturing and clinical staff, including the use of any device needed to deliver the cell therapy product. The first operational details to be worked out are those involving the timing of manufacture and the delivery to the patient. If the trial must be conducted at multiple sites, will there be a central manufacturing site or will processing staff need to be trained at each recruitment site?

Shipping and Administration of Cellular Products

Shipping is considered an extension of storage conditions. Selecting the right vendor is essential to shipping a stable product. The shipping containers purchased must be validated by the laboratory before their use. Transport documentation is a cGTP requirement for traceability of donor to final product purposes [1271.290(e)].[18] The U.S. Department of Transportation has guidance on classifying biologic materials in accordance with 49 CFR 171.[19]

Depending on the type of product, certain postshipment release testing may be indicated before its use. This requires cell therapy expertise at the receiving site or significant training. Shipping validation procedures can be conducted to determine what tests are required for certain products. Establishing postshipment acceptance criteria is critical for the use of many cell therapy products. Practice runs are recommended for shipment of the product, especially if the timing of the administration is crucial. For example, if a product is to be administered during a surgical procedure, it will be important to know the product viability if there are delays in shipment or postshipment testing or the surgical procedure.

In addition to a product meeting, the appropriate release criteria, the product administration process needs to be monitored. Patient baseline and postadministration evaluations are conducted, adverse events are documented, and any deviations from the product administration procedures or processes are recorded. Such documentation can allow the cell processing laboratory to evaluate common elements across different products as well as observe any product-specific trending.

Quality Control and Quality Assurance

A parallel process to the manufacturing process and preclinical studies is quality control (QC) and quality assurance (QA). QA begins before the manufacture of the cellular therapeutic begins. It is based on the manufacturing process and confirms that each step from raw material procurement to product release can be performed in a consistent and regulation-compliant manner. QC is product based and confirms whether or not the final cell therapy product satisfies the preestablished specifications for final release. Managers and third-party auditors are responsible for QA through the development of process documentation, establishing SOPs, conducting audits, and training. Inspectors and area supervisors perform QC by performing and receiving inspection reports at all points throughout the manufacturing process.

Data and Adverse Event Monitoring

In addition to the QC and QA of the cellular therapeutic, there is also the QC of data collection. Case report forms must be tailored to the study and need to be linked to the source data collected during the manufacture and delivery of the cells and throughout the clinical trial. The forms should be tested for ease of completion so that data coming in from the clinical sites will be easy to interpret. Data coordinators and research nurses should be given rigorous training on the completion of these forms and should know how long each form takes to fill out so they will be able to give a reasonable estimate of how many subjects they can follow within a given time period.

Whereas single-center trials are often monitored by an institutional data safety monitoring board (DSMB), multicenter trials typically have a centralized independent DSMB that is often convened by the sponsor (NIH or a pharmaceutical company). A monitoring plan must be developed for the collection and reporting of adverse events to the DSMB and the FDA. This is another step during which good communication is essential. The trial investigator and the cell processing facility must meet regularly to discuss any adverse events, especially events that occur during product administration, to determine if they are attributable to the cellular product or the subject's

underlying disease. The FDA and the DSMB must be informed of these events to determine if a prespecified stopping boundary has been crossed.

FUTURE DIRECTIONS

The development of novel cellular therapeutics is a long and complex process. There are many translational steps to be completed before exposure to humans is feasible. These steps range from practical issues such as the shipment of cells to the complicated issues of preclinical studies to be performed in multiple animal models. Investigators need to develop good working relationships with the cell processing facility staff and statistical staff in order to complete an effective clinical trial. All novel cell therapies and established cell therapies for novel indications require an IND application to be filed with the FDA. The key to a successful IND is early and frequent communication with the FDA.

CHAPTER 98

GRAFT ENGINEERING AND CELL PROCESSING

Adrian P. Gee

The abbreviation *BMT* has changed over the past few years from standing for bone marrow (BM) transplantation to denoting blood and marrow transplantation. This reflects the increased use of hematopoietic progenitor cells (HPCs) derived from cytokine-mobilized peripheral blood. It is fortunate that the abbreviation can also be used to cover stem cells derived from placental and umbilical cord blood, which represent the next new source of cells for transplantation. Other sources, such as adipose tissue, are being discovered, and each may provide cells with specific properties that can be exploited for different applications. The mobilization and collection of hematopoietic stem cells (HSCs) are discussed in Chapter 96. In this chapter, the ex vivo processing of these cells is reviewed. Processing may range from simple depletion of plasma or red blood cells (RBCs) to overcome ABO incompatibilities, to more complex procedures designed to engineer the graft components to enhance engraftment, prevent graft-versus-host disease (GVHD) or to introduce genetic modifications into the cells. Facilities performing these procedures are increasingly involved in other types of cellular therapies. These include provision of cells for adjuvant therapies in the posttransplant setting and to support clinical trials in regenerative medicine. The dramatic growth in these new applications has attracted the interest of regulatory agencies, which have worked hard to develop an appropriate strategy to address a complex new area of medicine. An understanding of the regulations is therefore essential because they are based on the type of cellular therapy product.

REGULATORY ISSUES WITH CELL PROCESSING

Regulation of a fast-moving field, such as cellular therapies, has posed a challenge to the U.S. Food and Drug Administration (FDA) and other national regulatory authorities. However, in the past few years, a risk-based structure has emerged in the USA that has clarified the strategy. In brief, manufacturers of cellular therapy products need to determine whether they fall under Investigational New Drug (IND) regulations, which require manufacturing of the product under good manufacturing practices (GMP); whether they fall under Part 1271 of Title 21 of the Code of Federal Regulations (21CFR) human cells, tissues, and cellular and tissue-based products (HCT/Ps), which require manufacturing of the product under good tissue practices (GTP); or whether they are exempt from both of these regulations.

The newer GTP regulations, which came into effect in May 2005, were established nominally to prevent the introduction, transmission, and spread of communicable diseases by HCT/Ps. This was based on the presumption that the majority of posttransplant infections and admissions to intensive care units were attributable to receipt of contaminated products. The basis of this statement is open to question, but the regulations provide a framework for screening, performing ex vivo processing, storing and distributing HCT/Ps, and providing the FDA with an overview of current activities by an annual registration of collection and processing facilities. The Part 1271 regulations effectively filled a gap in the law that left unregulated HCT/Ps that were minimally manipulated (e.g., were not cultured ex vivo, genetically modified, activated ex vivo), were intended for homologous use, or were not combined with another article (e.g., a matrix or scaffold) for administration. Minimally manipulated HCT/Ps should not exert a systemic effect and should not be dependent on the metabolic activity of living cells for their function. If this was not the case, then the cells should be for autologous use, for use in a first- or second-degree blood relative, or for reproductive use. Cellular products that fall into this classification are referred to as Type 361 products. The Part 1271 regulations do not apply to vascularized organs for transplantation; whole blood or blood components; and, important for this discussion, minimally manipulated BM for homologous use and not combined with another article.

With the exceptions noted, most other cellular therapy and HPC transplant products fall under IND regulations and are referred to as Type 351 products. These products have been cultured ex vivo and transduced or activated ex vivo and therefore are more-than-minimally manipulated. The facility processing these cells is required to operate under GMP. These regulations were originally developed for the pharmaceutical industry to ensure that drugs are manufactured under a controlled and auditable process that ensures their safety, purity, and potency. The FDA has indicated that the application of GMP to cellular therapy products follows a continuum, such that products that are manufactured for a phase I/II clinical trial under IND are not expected to be prepared under full GMP. As the trial proceeds the expectation is that the application of GMP will become more rigorous, such that a phase III product would be extensively characterized and manufactured using a fully validated process.

Implementation of Part 1271 regulations has had an impact on the "routine" laboratory that prepares cells primarily for hematopoietic transplantation. Laboratories that use cells other than BM now must register annually with the FDA; ensure that donors meet eligibility requirements (or document why noneligible donors are used); and manufacture, store, and distribute the cells under GTP. If a laboratory has previous experience manufacturing products for IND studies under GMP conditions, it already will be familiar with most of the features of GTP. In general, these cover personnel, procedures, facilities, environmental control and monitoring, equipment, supplies and reagents, recovery, processing and process controls, process changes, process validation, labeling controls, storage, receipt, predistribution shipment and distribution, records, tracking, and complaints. Implementation of the components of either GMP or GTP operations is a time-consuming process that requires the development, implementation, and maintenance of numerous components and generates a considerable volume of paperwork. Professional societies, such as the Foundation for the Accreditation of Cellular Therapy (FACT) and AABB (formerly the American Association of Blood Banks), have developed an accreditation process that takes into account GTP regulations and provides a framework around which compliance can be built (see Professional Standards).

An exception from the products described above is cord blood. In the United States, cord blood is a licensed product and facilities that prepare and bank cord blood will be required to request a Biologics License Application (BLA). This is permission to introduce or deliver for introduction a biologic product into interstate commerce (21 CFR 601.2). At the time of writing, the first American banks are undergoing this process.

Central to both GMP and GTP regulations is the establishment and maintenance of a quality program. This should ensure that the appropriate regulations are being followed on an ongoing basis; that

mechanisms are in place for detecting, reviewing, and remediating errors and deviations from regulations, policies, and procedures; and that an audit program will be developed and implemented. Evidence of the work of the quality program must be documented, and the program should ideally be staffed by individuals who are not involved in hands-on manufacturing of the products.

Holders of INDs must provide the agency with an annual report on the protocol and include a listing of the products administered and those that have been prepared but not used. In addition, cell processing facilities should be prepared to assist in reporting to the FDA information on products that have been associated with severe adverse reactions in the recipients. For Type 361 products, the facility must report, as Biological Product Deviations, any contaminated products that have been administered to a patient.

PROFESSIONAL STANDARDS

The two major accrediting organizations in the United States for cellular therapies are FACT and AABB. Whereas FACT offers accreditation of collection, processing, and clinical use of cellular therapy products, the AABB focuses on collection and laboratory processing. Both organizations inspect based on standards that are published every 18 months to 3 years. In the case of FACT, the standards are published in collaboration with the Joint Committee on Accreditation in Europe (JACIE). FACT also publishes separate standards in collaboration with NetCord that cover cord blood banking. Both organizations have worked to harmonize their standards with American, Canadian, Australasian, and European regulatory agencies; therefore, accreditation by either organization is of great assistance on the pathway to regulatory compliance. A number of other professional organizations accredit particular aspects of operations within the cell processing facility. These include the College of American Pathologists (CAP), which inspects general laboratories, hematology, and flow cytometry; the American Society for Histocompatibility and Immunogenetics (ASHI); and the European Federation for Immunogenetics (EFI), which accredits histocompatibility testing laboratories. Some organizations, such as CAP and StemCell Technologies, also provide proficiency testing services for laboratory staff.

MANIPULATION OF HEMATOPOIETIC STEM CELL TRANSPLANTATION PRODUCTS

Manipulation of a product for HSC rescue is intended to remove a component that is unwanted or may cause adverse effects or to enrich a desired population, such as CD34 cells. As discussed previously, the degree of manipulation may determine the regulations under which the product is manufactured and handled. The FDA defines minimal manipulation as processing that does not alter the relevant biologic characteristics of the cells or tissues. This includes procedures such as RBC and plasma depletion, and cell selection using an approved device. By contrast, more-than-minimal manipulation would include activities such as culture ex vivo, genetic modification, and ex vivo activation.

Routine Minimal Manipulation for Volume Reduction or ABO Incompatibility

The most widely used form of manipulation in the HPC processing facility probably is removal of erythrocytes or plasma (or both) to overcome ABO incompatibility between donor and recipient (Table 98-1). This process is performed using techniques that were developed by the blood banking industry.

Plasma depletion to remove donor antibodies that may react with recipient cells is achieved by centrifugation of the graft, usually in a transfer pack, at approximately 2000 g for 10 minutes at ambient temperature. The pack then is placed in a plasma expresser, which compresses the product bag so that plasma can be forced out and into a separate collection bag. Plasma depletion can also be used to reduce the volume of ABO-compatible grafts when the donor is large and the recipient small.

Table 98-1 Processing Performed to Address ABO Incompatibilities Between Hematopoietic Stem Cell Donors and Recipients

Recipient ABO Type	Donor ABO Type	Type of Processing
ABO identical	ABO identical	No special processing required
A or B	AB	RBC depletion
O	A/B/AB	RBC depletion
A	B	RBC + plasma depletion
B	A	RBC + plasma depletion
Antibody to RBCs	N/A	RBC depletion
A/B/AB	O	Plasma depletion
AB	A or B	Plasma depletion

N/A, Not applicable; *RBC,* red blood cell.

Red blood cell depletion removes incompatible donor erythrocytes that would stimulate a reaction by the donor upon administration. Most facilities establish a maximum volume of incompatible RBCs that can be infused with HPC; exceeding this limit can result in hemolysis and a transfusion reaction. Depletion of erythrocytes can be achieved most simply by centrifugation. The product is centrifuged at approximately 3000 g for approximately 10 minutes at ambient temperature, and the leukocyte-rich buffy coat is collected at the interface between the plasma layer and the RBCs.

Red blood cell depletion can also be achieved by sedimenting erythrocytes using hydroxyethyl starch (hetastarch). This promotes RBC sedimentation by formation of erythrocyte rouleaux. The hematocrit of the product is first adjusted to 25% by addition of normal saline, and 6% hetastarch (Hespan) is added at a volume:volume ratio of 1:6 to 7. Sedimentation can be performed under gravity or may be accelerated by centrifugation.

The most rigorous erythrocyte depletion is achieved by centrifugation of the collection on a Ficoll-Hypaque density gradient. This process enriches mononuclear cells at the interface between the gradient and the layered cells after centrifugation and depletes erythrocytes, platelets, and granulocytes. As a result of enrichment for mononuclear cells, the overall nucleated cell recovery is lower than with other techniques.

Automated devices are available for preparing buffy coats and density gradient-enriched cells. For larger volumes, the COBE 2991 Cell Processor from Terumo can be used. This requires a minimum volume of 150 mL RBCs for operation and may therefore not be suitable for pediatric processing. It is capable of preparing buffy coats and density separated cell preparations using a functionally closed disposable set.

The COBE Spectra from Terumo is in common use to collect peripheral blood progenitor cells by apheresis. The device is also less widely used in the processing facility to enrich mononuclear cells from BM. A similar procedure and density gradient separation can be performed on the CS3000 separator from Fenwal Blood Technologies.

For smaller starting volumes, the Sepax device from Biosafe can be used (Fig. 98-1). It has found widespread application in cord blood banks for buffy coat preparation (with or without hydroxyethyl starch) and has also been used for volume reduction of peripheral blood progenitor cell collections, density gradient separation of BM and for cell washing. The device has a small footprint, uses functionally closed disposables, and provides a print-out of operations.

Xpress devices for cord blood and marrow processing are available from Thermogenesis. The AXP AutoXpress is designed for enriching

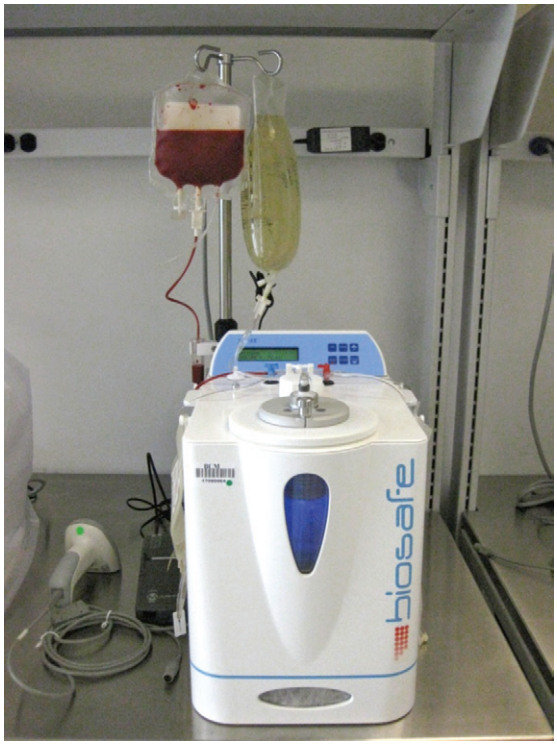

Figure 98-1 THE BIOSAFE SEPAX DEVICE. Used for automated processing of hematopoietic cells.

mononuclear cells from cord blood that is transferred to the processing set, which is then placed into the AXP device. This fits into a centrifuge bucket, and during spinning, the red and mononuclear cells are collected into separate bags and the plasma is retained in the processing set. The MarrowXpress performs a similar procedure on marrow harvests. Both devices provide closed sterile systems, and the XpressTRAK software enables data tracking to assist with regulatory compliance.

Purging of Autologous Grafts

Autologous HPC can be used for recipients lacking a human leukocyte antigen (HLA)-matched related or unrelated donor. It has been proposed that occult viable tumor cells collected with the graft and returned to the patient could act as a source for disease relapse. Gene marking studies have supported this hypothesis. As a result, much effort has been exerted to develop methods for the ex vivo detection and removal of tumor cells from autologous grafts. Techniques have included incubation with chemotherapeutic drugs, such as 4-hydroperoxycyclophosphamide (4-HC), photosensitizing agents, and antisense oligonucleotides. Alternatively, tumor-directed monoclonal antibodies (MAb) can be used to identify the cells and effect their removal. The MAb-coated tumor cells can be eliminated by addition of serum complement or by capturing them on a solid phase, such as a column matrix, a plastic sheet, or magnetic particles. These particles may be large (5 μm diameter) so they can be collected, with the attached tumor cells, in a standard magnetic field. The matrix material may be much smaller, such as nanoparticles or ferrofluids, which coat the cells. These are then collected on a metal matrix placed in a field generated by permanent magnets. Such systems are capable of depleting 4 to 6 logs of tumor cells from a graft. However, even at such high efficiencies, given the limits of our ability to detect residual tumor cells, the clinical value of purging autologous grafts is debatable. There has been a decline in interest in purging techniques because of the potential benefits of a graft-versus-tumor (GVT) effect detected in recipients of allogeneic grafts.

T-Cell Depletion of Allogeneic Products

T cells in HPC grafts have the potential to cause severe or lethal GVHD or potentially to exert a beneficial GVT effect (discussed in Chapter 109). Considerable work has been done to determine whether these opposing effects are produced by distinct subpopulations of T lymphocytes. This would allow ex vivo manipulation of allogeneic grafts to remove differentially the GVHD-producing T cells while sparing those that mediate GVT responses. Various subpopulations of T cells have been identified as candidate effector subpopulations; however, there is no widespread consensus as to which subsets should be targeted.

Methods are available for eliminating T cells from grafts using approaches similar to those used for purging tumor cells. Early approaches included use of soybean agglutinin to aggregate the majority of nonprogenitor cells and rosetting of sheep erythrocytes with T cells to facilitate their removal. Although successful, these techniques are not "FDA friendly" and do not offer the specificity that likely is required to engineer T-cell subpopulations in allogeneic grafts. This is possible by use of MAb directed toward the antigens that currently are used to identify T-lymphocyte subpopulations. The target population then can be removed with high efficiency using immunomagnetic separation, as described previously for purging autologous grafts. The challenge remains to identify the appropriate target T cell populations and to source clinical grade MAb for these procedures. A number of potential target antigens have been identified and separation techniques implemented. They range from pan–T-cell depletions using antibodies to CD3 and CD2, to depletions of helper and cytotoxic T cells using monoclonals against CD4 and CD8, to stimulation and removal of alloreactive populations by targeting activation antigens.

Methods that eliminate or physically remove either T cells or tumor cells from grafts are referred to as *negative selection techniques*. They are affected by variables such as target antigen expression, sensitivity of detection technologies for quantitating separation efficiency, and other technical hurdles. They may be difficult to manipulate to achieve the ideal composition of the graft and the target level of T cells remains to be established, although the figure of 105 T cells/kg is generally regarded as the goal to minimize the risk of GVHD while facilitating engraftment. There are also no approved devices for negative selection, so these types of procedures must be performed under an IND.

For many years, the goal was to replace negative selection with a procedure in which HPC populations could be specifically enriched by positive selection. This would effectively deplete T cells and tumor cells from allogeneic and autologous graft, respectively. The problem was the lack of a method for identifying the target HPC until the CD34 antigen was identified on a small population of progenitor cells, including the pluripotent cells required for hematopoietic transplantation. The subsequent availability of monoclonal antibodies directed against this antigen made possible the development of techniques for enrichment of cells. Immobilization of the antibodies on a matrix (e.g., plastic sheets) and cellulose and magnetic particles was used as the primary approach, and a number of devices were commercially developed. The first to achieve FDA approval for use with apheresis products was the Baxter Isolex 300i, which uses Dynal 5-μm magnetic beads as the separation modality and releases $CD34^+$ cells from the beads using a competitive binding peptide. This device was recently withdrawn from the market for this application and is currently under evaluation for use in regenerative medicine protocols.

An alternative is the CliniMACS system (Fig. 98-2), which currently has regulatory approval in Europe but still requires an IND for use in the United States. This uses anti-CD34 nanoparticles to effect separation. The labeling and removal of unbound CD34 reagent is performed manually. The CD34 reagent-treated cells are then processed on the device, where they are retained on a column located in a high-gradient magnetic field. Nonlabeled cells flow through the column and are collected in the negative fraction. The labeled cells are recovered from the column after several automated separation and

washing cycles by removing the magnetic field. The nanoparticles remain on the CD34-positive cells; however, they are biocompatible and may be infused into the recipient. The device normally achieves purities in excess of 90% with yields of approximately 60%. This results in passive depletion of 4 to 6 logs of T cells. The device may be used with a variety of MAb directed against antigens expressed by various types (T, B, and natural killer [NK] cells), potentially allowing it to be used as a platform for multiple types of graft engineering.

Positive selection techniques may also passively deplete from the graft certain cells that could be of potential benefit to the recipient. These include some stromal elements, GVT-mediating T cells, and other subpopulations that may facilitate engraftment. As our understanding of the identity of these populations improves, it may be possible to recover them from the normally discarded negative fraction and add them back to the CD34+ cells or to use them in the posttransplant period as donor leukocyte infusions (see later discussion).

Table 98-2 lists various methods of direct T-lymphocyte depletion and indirect depletion by HPC enrichment.

EVALUATION OF MANIPULATED GRAFTS

Most allograft engineering has focused on T-lymphocyte depletion and has emphasized quantitative versus qualitative removal. The majority of allografts are infused immediately after preparation rather than after cryopreservation and storage. This restricts the types of assays that can be used to evaluate graft composition to those that have a rapid turnaround, and the implications of infusing large numbers of T lymphocytes can be severe or lethal. Therefore, it is important to have available methods that can rapidly enumerate the numbers of T lymphocytes within the graft. Although early methods used detection of E-rosette–forming cells or manual immunofluorescence after staining with pan–T-lymphocyte–directed monoclonal antibody, most laboratories currently rely on flow cytometry. This technology is widely used in routine clinical laboratories; however, some precautions must be taken when it is used for T-depleted allografts.

Flow Cytometry

Accurate enumeration of very small numbers of target cells by cytometry requires rare event analysis. In this technique, large numbers of events must be accumulated and carefully analyzed if reliable data are to be obtained. This approach has been widely adopted for counting $CD34^+$ cells in unfractionated grafts but still is often neglected when enumerating T lymphocytes in depleted grafts. The choice of MAb for detection of the T-lymphocyte population also is critical when a MAb-mediated depletion technology is used. The same MAb should not be used for both depletion and analysis because cells that became coated with the antibody during the depletion phase but were not effectively removed will be blocked from detection. However, they can be detected by adding an anti-immunoglobulin antibody conjugated to a fluorochrome different from the one conjugated to the T-lymphocyte–directed MAb. The most sensitive detection is achieved by using panels of non–cross-blocking anti–T-lymphocyte antibodies directed against a variety of epitopes.

It is important to include a viability stain in the analysis panel. Although this is less crucial when T-lymphocyte depletion is achieved by physical removal of target cells, it is extremely important when in situ elimination methods are used. In these cases, the depleted allograft may contain dead or dying T lymphocytes that will be detected by flow but may not contribute to postinfusion events. Suitable viability stains include propidium iodide and 7-aminoactinomycin (7-AAD). Analysis of cell viability after ex vivo depletion is not straightforward. Cell death may not be expressed immediately but develops in the hours or days after processing and infusion. Under such circumstances, the analysis of apoptotic cells by a combination of Annexin-V staining with 7-AAD may provide a more accurate estimate of cell damage. This approach can be used in combination with simultaneous staining for T-cell surface markers to provide additional information. In some cases, incubating the cells for a period before analysis is advisable (e.g., in the case of depletion by immunotoxins, cells require time to divide to manifest the toxic effects). Stimulation of cells with interleukin-2 (IL-2) and ex vivo culture also has been used to detect functional residual T lymphocytes. In some cases, this method has shown a correlation between the numbers of T lymphocytes in the cultured sample and the development of clinical GVHD in the graft recipient.

Tetramer Analysis

Enumeration of T cells bearing receptors for specific antigens can be achieved using tetramer analysis (Fig. 98-3). In this procedure, soluble versions of heavy chain of major histocompatibility complex (MHC) molecules are synthesized and adopt the appropriate conformation when a synthetic peptide representing the epitope is recognized by the T-cell receptor (TCR) and β2-microglobulin is added. The carboxyl-terminus of the MHC molecule is biotinylated, and four of these peptide/MHC–biotin complexes assemble into a

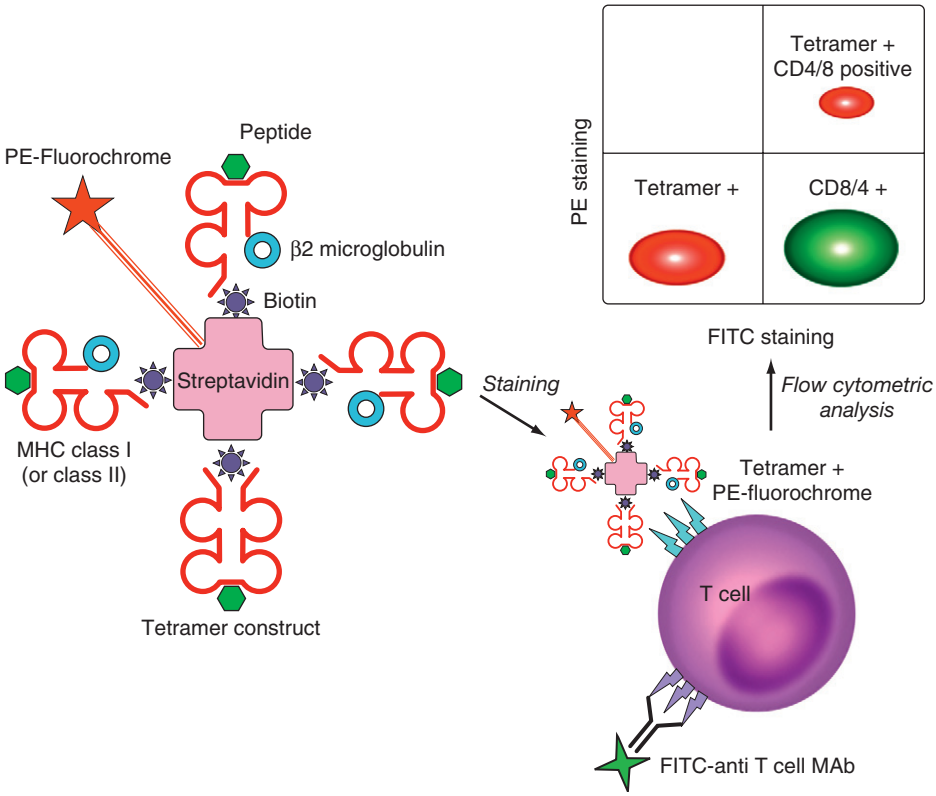

Figure 98-3 TETRAMER STAINING TO DETECT ANTIGEN-SPECIFIC T CELLS (SEE TEXT FOR DETAILS). *FITC,* Fluorescein Isothiocyanate; *MHC,* major histocompatibility complex; *PE,* Phycoerythrin.

tetramer when streptavidin is added. The streptavidin is tagged with a fluorochrome; therefore, T cells reactive with the chosen peptide–MHC complex become fluorescently stained and can be detected by flow cytometry.

Functional Assays

Flow cytometry detects residual cells by their ability to bind monoclonal antibodies. Routine flow does not provide information on the functional capacity of these cells, which may be important when assessing the graft for its potential to mediate GVHD or GVT. For this purpose, a number of assays have been developed. These are not suitable for use as release tests because of their turnaround time, but they can provide retrospective information that may correlate with clinical outcome. They include limiting dilution analysis, in which a range of dilutions of the graft are plated out and assessed for the ability of T cells to form colonies in response to the addition of stimulants, such as phytohemagglutinin (PHA) and IL-2. Based on the proportion of colony-forming wells at the various dilutions, it is possible to determine by the Poisson distribution the number of T cells present in the original graft.

Another approach is use of an enzyme-linked immunosorbent spot (ELISpot) assay in which cells are stimulated to produce an analyte that is characteristic of their normal function. The cells are plated onto a surface that has been coated with an antibody directed against that analyte and incubated for a fixed period. The secreted analyte binds to this antibody, and the cells and any other unbound material are washed away. The surface is incubated with a biotinylated antibody directed against the analyte and washed and incubated with alkaline phosphatase linked to streptavidin. After washing, the plate is incubated with a substrate solution. A blue-black precipitate will appear at sites were the analyte was produced, with each spot representing an analyte-secreting cell. The spots can be enumerated manually or by using an ELISpot reader.

CELLULAR THERAPY PRODUCTS

A number of cellular therapy products, including some that have been genetically modified, are being evaluated in clinical trials (see Chapter 95). These have examined the safety and efficacy of different cell populations, including, but not limited to, unmanipulated leukocyte infusions from HPC donors, cytokine-induced T cells, lymphokine-activated killer (LAK) cells, tumor-infiltrating lymphocytes (TILs), T-regulatory cells, antigen-specific T cells (see Chapter 101), mesenchymal cells (see Chapter 100), dendritic cells (DCs) (see Chapter 103), and NK cells (see Chapter 102). Detailed accounts of the scientific basis for such studies as well as results of clinical trials are given in Chapters 95 and 97. This section focuses on processing and product evaluation issues.

Cells that have been more-than-minimally manipulated must be prepared under GMP conditions. This requires that manufacturing be performed by trained staff following formal standard operating procedures. These procedures will have been submitted to the FDA in the chemistry, manufacturing, and control (CMC) section of the IND application and will specify how the product is prepared, the reagents and materials that will be used, and the criteria for the release of the product for clinical use. Release criteria are test specifications that are designed to ensure that the product is sterile and pure, and they may include assays for functionality. The specific tests for sterility and purity that have been approved by the FDA are described in 21CFR 610.12, and a number of guidances have been issued by the FDA on the use and validation of alternative techniques. The CFR assays are generally considered to be outdated; however, the Agency indicated in June 2011 its intent to amend the sterility test requirements for biologic products. They would eliminate the prescribed methods in CFR 610.12 and allow the use of alternative validated methods. If the proposed test method is an established U.S. Pharmacopeia compendial sterility test, then formal validation is considered to have been already completed. This should considerably simplify and reduce the costs of sterility testing.

In the normal release mechanism for a cellular therapy product, the quality unit reviews the production records and issues a certificate of analysis (CofA) (Fig. 98-4). This document details the testing that was performed together with test method, the testing laboratory, the specification required by the FDA, and the actual results obtained. Routine testing required for most cellular therapy products consists of aerobic, anaerobic, and fungal sterility; endotoxin levels (by Limulus amebocyte method); mycoplasma for ex vivo expanded cells (assayed by the culture method); identity and purity (by flow cytometry and, in some cases, HLA typing); and, for products in later stages of evaluation, functionality (e.g., cytotoxic activity toward target cells or secretion of specific bioactive products). Products that have been transduced with a retroviral vector will also require testing for replication-competent virus. Use of non-FDA approved test methods should be cleared with the FDA at the IND application stage. In most cases, regulatory agencies also like to see some form of stability testing program that evaluates the stability of the cellular product over time in storage in the frozen state and when thawed for administration.

Phase I studies are designed to assess the safety of the product and should include assessment of reactions to infusion, risks for contamination during preparation, and delayed effects after administration. Clinical efficacy is evaluated during phase II/III. At this time, progress should be made toward the development of an in vitro assay for functionality that correlates with clinical efficacy. This can be problematic because most in vitro assays currently used are unreliable as predictors of the clinical value of the product, and some form of surrogate marker has been substituted.

Donor Leukocyte Infusions

The ability of infusions of donor leukocytes (DLI) to mediate antitumor responses was originally described in patients with chronic myeloid leukemia (CML) in hematologic relapse after allogeneic stem cell transplantation (SCT), but lymphomas and Hodgkin disease also are sensitive to the effects of DLI. Remission rates of up to 80% have been reported in CML patients who relapse after transplant. Up to 90% responses have been described in patients with Epstein-Barr virus (EBV)–associated lymphoproliferative disease. Moderate success has been achieved with use of DLI after relapse in other malignancies such as acute myeloid leukemia (15%-40%), low-grade lymphomas (≤60%), and metastatic multiple myeloma (40%-60%). Fewer than 5% of patients with relapsed acute lymphoblastic leukemia respond

CERTIFICATE OF ANALYSIS

Center for Cell & Gene Therapy, GMP Cell Processing Facility
Baylor College of Medicine, Houston, Texas 77030

Retrovirally Transduced Donor Leukocytes
Depleted of Alloreactive T cells by Anti CD25-Immunotoxin (RFT5-DGA)
Caution: New Drug-Limited by Federal Law to Investigational Use
Properly identify intended Recipient and Component

Recipient Name: DOE, Jane
Recipient MR #: TCH 123456
Recipient CAGT Number: P2669
Donor Name: DOE, John (TCH789101)
Component CAGT Number: C1234.A.61
Date Frozen: 08/21/2011
Store at temperatures below -150°C

TEST	LABORATORY	SPECIFICATION	RESULT
Viability – Cell product (Trypan Blue dye exclusion)	CAGT GMP Facility	> 70% viable	99% viable *08/21/11*
Endotoxin – Cell supernatant (LAL assay by Endosafe)	CAGT QC Laboratory	≤ 5.0 EU/ml	<2.0EU/ml *08/25/11*
Bacterial Sterility – Cell product Bactec – aerobic Bactec - anaerobic	Clinical Laboratory Services, The Methodist Hospital, Houston	Negative (at 14 days)	 Negative *09/05/11* Negative *09/05/11*
Fungal sterility – 1st wash Bactec	Clinical Laboratory Services, The Methodist Hospital, Houston	Negative (at 28 days)	Negative *10/21/11*
Mycoplasma – Cell product (PCR assay)	CAGT QC Laboratory	Negative	Negative *08/31/11*
Phenotyping (Flow cytometry)	CAGT GMP Flow Facility	< 1% CD25+ cells	0.03% CD25* *08/21/11*
Proliferation in Primary Mixed Lymphocyte Culture – Cell Product	CAGT 7th Floor Labs.	<10% proliferation	3% proliferation *08/13/11*
Replication-Competent Retrovirus (Extended S+L- assay for GAL-V pseudotyped virus)	Vector Production Facility, University of Indiana	Sample sent for testing	Sent for testing *09/23/11*

Figure 98-4 SAMPLE CERTIFICATE OF ANALYSIS USED FOR THE RELEASE OF CELLULAR PRODUCTS MANUFACTURED UNDER AN INVESTIGATIONAL NEW DRUG.

to DLI alone. Although the etiology is unclear, the reason could be lack of antigenic expression, downregulation of T-cell recognition molecules, or tumor burden at the time of treatment.

The regulatory situation for DLI is complicated and probably is in transition. At present, nonmanipulated DLI are classified as Type 361 products and fall under Part 1271 of 21CFR. It is possible that they will be reclassified as Type 351 products requiring an IND application. Currently, formal release criteria are not required; however, the normal practice is to evaluate T-cell content by flow cytometry and to test for sterility. This may be done by a Gram stain (used for immediate release) accompanied by culture-based methods. These provide results after the product has been infused. Formal procedures should be in place to inform the recipient's physician if a positive test result is subsequently received. The contaminant should be speciated and antibiotic sensitivities obtained and communicated to the physician. DLI that have been manipulated ex vivo in any way (e.g., by targeting them to specific antigens or by transduction with a suicide gene, as described later) will be classified as Type 351 products requiring an IND. These products will require formal release testing as described previously for other cellular therapy products.

Nonspecifically Activated Autologous T Cells

T cells can be expanded ex vivo through polyclonal activation using PHA, anti-CD3 antibody, or a combination of anti-CD3 and anti-CD28 antibodies. Several groups have evaluated whether such expanded T cells have antitumor activity. Faster recovery of lymphocyte counts with improved outcome after autologous transplant observed in non-Hodgkin and Hodgkin lymphoma led to a phase I study evaluating infusion of autologous CD3/CD28 activated cells after a CD34-selected SCT.

Cells prepared for these types of studies are Type 351 products because they are cultured ex vivo and may have undergone some form of activation. Manufacturing must be carried out under GMP, and the clinical studies must be performed under an IND. The IND application must describe in the CMC the procedure for manufacturing the cells and the criteria that will be used to determine whether they can be released for clinical use. Many manufacturing procedures use reagents and materials that are not approved for human use, and the application should include information about these materials and what testing will be performed before they can be used for manufacturing the clinical product. Justification should be provided for the use of nonapproved media and supplements and any potentially undesirable ancillary products, such as antibiotics. Evidence should be provided on the efficacy of their removal before administration of the product.

The release criteria for autologous T-cell products are similar to those described for generic Type 351 products. They include tests for sterility, endotoxin, mycoplasma, and identity and purity (i.e., by flow cytometry); some test of functionality is recommended but is not usually required for phase I studies. A draft of the CoA, which will be used for release, should be included in the IND submission.

Tumor-Infiltrating Lymphocytes

Tumor-infiltrating lymphocytes are cells harvested from tumor sites and are expanded ex vivo with IL-2. As the cells are being expanded, increased tumor specificity is achieved by pulsing the cells with tumor-specific peptides or transducing them with a retrovirus encoding a tumor-specific TCR. A major limitation is that patients must have preexisting lymphocytes that can both respond to tumor and be expanded ex vivo; however, in studies, transfer of these cells led to tumor regression in 50% of lympho-depleted patients with metastatic melanoma.

A number of methods have been developed for isolation of TIL from tumors. They include mechanical disruption, enzymatic treatment, differential centrifugation approaches, and positive immunomagnetic selection. The method of choice depends on the type of tissue from which the cells are to be extracted and the availability of reagents, such as MAb, targeting the T-cell population of interest. As with T-cell depletion of allogeneic grafts, the predominant effector TIL cell population is not fully characterized, and the availability of this information should facilitate the design of more effective separation techniques. A number of approved enzymes and centrifugation media are available, and several companies have suitable MAb that have been prepared under GMP conditions but have not been submitted for FDA approval.

The extracted cells are expanded ex vivo, usually starting in semi-open systems such as cluster plates. The initial populations may be tested in a cytotoxicity assay in an attempt to identify the effector population, which can then be selected for expansion. The expansion phase usually progresses through a number of types of cultures as cell numbers increase. These may progress from plates to T flasks and gas-permeable bags to hollow fiber and culture bag bioreactors. The culture medium contains IL-2 as the primary cytokine, although other agents alone and in combination may be used to promote outgrowth of specific cell subpopulations.

Some investigators have used irradiated tumor cells to restimulate TIL during culture; others have performed selective separations to enrich the effector cells during expansion. Highly characterized tissue culture media, such as the serum-free lymphocyte medium AIM V, have been used for expansion. The goal is to use the simplest medium with the fewest additives that will support growth of functional cells. When possible, the media should be free of animal serum and proteins to simplify the regulatory issues. However, the FDA is aware that complex media and serum combinations may be required to support growth of some cell types and is willing to consider them, particularly if the cells can be washed into an approved carrier for administration.

Initiation of a phase I study using TIL or TIL subpopulations will not require complete characterization of the effector cell population, but some preliminary information should be available that allows quantification of the putative effectors for dosing. In most cases, flow cytometric analysis will be used, and the target antigens may be pan–T-cell markers or specific combinations of T subset markers. When other constituents of the product may adversely affect the activity of effector cells, it may be necessary to set an upper limit for contamination by these cells in the clinical product. Most facilities perform some type of functional assay as a part of the release process, which in the case of TIL may be cytokine release or cytotoxic activity toward tumor cells of the appropriate histologic type.

Allodepleted Cells

The major drawback of DLI is the significant risk of GVHD, which is the most important source of treatment-related mortality. Given that the frequency of tumor or viral antigen-specific T cells in most cases is considerably lower than that of alloreactive T cells, it is necessary to expand antigen-specific T cells ex vivo not only to enhance antitumor activity but also to try to separate GVHD from GVT effect. An alternative method for separating GVHD from GVT effect is to selectively deplete alloreactive donor T cells ex vivo. Selective allodepletion is performed by removing donor T cells that express activation markers after coculture with nonleukemic recipient cells. Activation markers investigated include CD25 and CD69 and the increased sensitivity of activated T cells to photosensitizing dyes. A number of phase I/II studies using immunotoxin directed against CD25 have demonstrated the feasibility of this approach, with accelerated reconstitution of virus-specific and total T-cell numbers and low rates of severe GVHD. Relapse rates remained high in this study, which probably reflects the high-risk nature of the patient population.

Potential recipients of allodepleted cells often receive a CD34-selected HPC graft. As a part of the CD34 selection process, a negatively selected population of cells that includes T cells becomes available. However, this fraction usually is not used as the source of cells for allodepletion. These cells usually have been obtained from donors who received granulocyte-macrophage colony-stimulating

factor (GM-CSF) for mobilization of peripheral blood progenitor cells, and during processing for CD34 selection, they were exposed to anti-CD34 monoclonal antibody. Therefore, it is preferable to obtain cells for allodepletion from a peripheral blood draw of the donor before administration of growth factor for mobilization. The T cell–enriched fraction usually is obtained by centrifugation on a Ficoll-Hypaque density cushion. The cells are washed and co-incubated with irradiated recipient mononuclear cells, which act as stimulators. A convenient source for stimulator cells is obtained by generation of a cell line from the donor by infection of his or her peripheral blood mononuclear cells with a laboratory strain of EBV. The co-incubation step produces stimulation of alloreactive donor T cells with resulting expression of activation markers, which then can be targeted to remove the alloreactive population. Methods for elimination include cytotoxic drugs (e.g., methotrexate), anti-CD25 monoclonal antibody conjugated to the toxin ricin, and immunomagnetic selection. All of the regulatory issues associated with the manufacturing and release of Type 351 products apply to allodepleted T-cell products. Release criteria include routine assays for sterility and purity. HLA typing may be included as a confirmation that the cells in the product are of donor origin. Functional assays may include demonstration that the allodepleted cells fail to proliferate when cultured in a primary mixed lymphocyte reaction (MLR). If a suicide gene has been introduced (see below), testing will include demonstration that it can be efficiently activated.

Suicide Gene Transduced Lymphocytes

Although treatment with DLI has led to remission in patients with disease after HSC transplantation, unmanipulated cells also contain alloreactive T cells and can induce GVHD. The incidence of GVHD ranges from 55% to 90% and is associated with a treatment-related mortality rate of about 20%. Approaches that maintain the GVT effect while decreasing the incidence of GVHD have been evaluated and include transduction of donor T cells with a "suicide gene." Genes can be introduced into DLI or alloreactive-depleted cells to express the herpes simplex virus-1 thymidine kinase (HSV-tk). If GVHD develops, ganciclovir is administered to the recipient, resulting in suicide of the transduced donor leukocytes.

Alternative suicide genes based on the dimerization of Fas or Caspase-9 in the apoptotic pathway have been developed to circumvent the problem of immunogenicity of HSV-tk. The inducible Caspase construct also encodes a selection marker, such as CD19, that can be used to enrich the transduced population. In the event that GVHD develops after administration of the Caspase-transduced cells, the suicide activation drug can be administered to the recipient to eradicate the transduced T cells by dimerization of Caspase 9 and activation of the apoptosis pathway.

Antigen-Specific Cytotoxic T Lymphocytes

Two major prerequisites for generating antigen-specific cytotoxic T lymphocytes (CTL) are the identification of appropriate viral or tumor target antigens and the availability of suitable antigen-presenting cells (APCs). After being identified, CTL lines can be generated by coculturing T cells with APC that express the target antigen. The lines are then expanded by restimulation with the antigen of choice and the addition of cytokines such as IL-2.

To generate antigen-specific CTLs, it is necessary to have a good source of APCs and a source of antigen to present to T cells. A variety of APCs have been evaluated, including fibroblasts, monocytes, and DCs, using different sources of antigen, including virus lysate or lysate of antigen-positive cells, peptides, or transduction of the APC, such as lymphoblastoid cells (LCLs) and DC with an immunodominant antigen. Use of lysates as the antigen source can be problematic because they are likely to be variable and difficult to standardize. Alternatively, many processing laboratories may not be experienced in handling virus and virus-infected cells.

Lymphoblastoid cells prepared using laboratory strains of EBV make excellent APCs for use in manufacturing EBV-specific T cells. They present EBV antigens efficiently, and they express high levels of costimulatory molecules. The normal procedure for generating the LCL is co-incubation with EBV derived from the tamarin B95-8 cell line. This line has undergone extensive testing and has been approved for use as a source of "clinical" EBV. The resulting LCLs are cultured in media containing acyclovir to eliminate any residual EBV. The LCLs are used to repeatedly stimulate T cells (as a mononuclear cell fraction of peripheral blood leukocytes), resulting in a population that is directed toward the immunodominant EBV antigens. These CTLs can be frozen while release testing is performed. They are delivered frozen to the bedside, where they are thawed and administered intravenously. Release testing consists of the routine tests described earlier for Type 351 products. For allogeneic CTL, functionality usually is assessed by cytotoxicity assays, which must demonstrate less than 10% killing of autologous PHA blasts.

One limitation of this approach is that expansion of virus-specific T cells to achieve adequate dose levels is extremely time consuming. All of these procedures require several weeks to generate APCs. One means of overcoming this problem is to manufacture banked allogeneic EBV-specific CTLs so that an "off-the-shelf" product is available. Clinical responses have been described for patients who received partially matched allogeneic CTL. The generation of banks of CTL requires careful donor screening and HLA typing and the manufacture of products with a sufficiently wide range of HLA types to allow at least partial matching with the intended recipient.

Natural Killer Cells

Natural killer cells are effectors from the innate immune system that also mediate antiviral and antitumor immunity. Studies have shown that haploidentical NK cells infused after lymphodepleting chemotherapy can have antitumor effects. Most facilities use a simple positive selection with clinical scale immunomagnetic methods involving CD56 selection or CD3 depletion for such products. These procedures must be done under an IND because of lack of commercially available devices and reagents for this indication.

When preparing an IND application for NK cell enrichment, care should be taken to ensure that the MAb used for the selection or depletion are of the highest quality available. CofA for these reagents should be submitted with the IND application, and the agency probably will require detailed information on their manufacturing (i.e., to ensure that the process includes robust procedures for virus inactivation or removal). The same type of information may be required for any ancillary reagents (e.g., buffers and protein sources used to supplement buffers). Preclinical data demonstrating that the enrichment technique is effective should be provided and accompanied by data from clinical scale validation enrichments, providing evidence that the NK cells can be separated with acceptable viability, purity, and yield for the proposed study. The CMC section of the IND application should include information on the methods used to store, label, and administer the cells. Engineered APCs, such as the K562-mb15-41BBL cell line, if used to stimulate NK cells, should initially have been grown and tested as a Master Cell Bank, from which a Working Cell Bank is generated and tested for routine use.

Dendritic Cells

Dendritic cells are powerful APCs that can be used in vitro or in vivo to elicit immune response to the antigen they are presenting. A number of studies have evaluated tumor antigen-primed DCs for treatment of hematologic malignancies and solid tumors. Antigen-primed DCs are used to target T cells in vitro toward specific antigens. These cells then can be used therapeutically to eliminate viruses or tumor cells bearing that antigen. DC can be derived from BM or cord blood and mobilized and resting peripheral blood obtained from normal donors and patients. The normal procedure consists of

enriching monocytes from the source material, which has been accomplished by plastic adherence or CD14-based immunomagnetic selection (or by depletion of $CD19^+$ B cells and $CD2^+$ T cells). An alternative approach is use of elutriation to collect an enriched monocyte fraction from the donor. A purpose-built elutriation system for collection of monocytes is available (the Elutra). This method also has been used successfully to enrich monocytes from cryopreserved mobilized apheresis collections.

The monocyte fraction can be cultured in polystyrene tissue culture flasks or gas-permeable bags in culture medium containing IL-4 and GM-CSF) to induce DC differentiation. This is followed by culture in medium containing proinflammatory mediators to accelerate maturation. A number of supplements have been used during this phase, including CD40 ligand or poly(I:C), interferon-α, tumor necrosis factor-α, IL-6, IL-1α, and prostaglandin E_2. Some protocols add proinflammatory mediators at the initiation of the cultures rather than after induction of differentiation. One issue for facilities is finding clinical or GMP-grade cytokines and growth factors. Some sources now are available, and many manufacturers assist investigators by providing information on test procedures and stability information. Attempts have been made to expand DC in serum-free medium with varying degrees of success; improved growth and maturation have generally been obtained in the presence of human AB or autologous serum. Of note, minor changes in composition of the culture medium and even in the type of vessel used for culture have been reported to affect the yield, phenotype, and functional activity of the resulting DCs. Cultured DCs have been effectively transfected using native tumor DNA or lentiviral or adenoviral vectors. The cells can be cryopreserved for later administration or use.

Assessment of DC product usually involves immunophenotyping ($CD1a^+$, $CD80^+$, $CD83^+$) and some type of functional assay (ability to generate an allogeneic T-cell response or response to a recall antigen as measured by proliferation assay) in addition to the standard release assays.

Mesenchymal Stromal Cells

Mesenchymal stromal cells (MSCs) are cells with multilineage potential that have shown efficacy in promoting engraftment and suppressing GVHD. They are also being widely used in regenerative medicine applications. In vitro MSCs are capable of differentiating into bone, cartilage, cardiac and skeletal muscle, neuronal cells, adipose and connective tissue, and tendons. The cells are not inherently immunogenic and do not appear to be recognized by allogeneic T cells or NK cells. They express very low levels of MHC class II and intermediate levels of class I antigens. They appear to be able to suppress in vitro T-cell proliferation and function of both memory T and naive T cells and to inhibit the development of monocyte-derived DCs in vitro.

A number of technical variables affect MSC culture and expansion ex vivo. They include culture medium, passaging density, serum type and concentration, population selection, culture vessel, and use of growth factors. To reduce some of this variability and reduce the costs of preclinical testing, the FDA often encourages investigators to adopt a manufacturing process that is in current clinical trials. The following is a basic procedure. MSCs usually are isolated from BM collected from the iliac crest. The cells are diluted, and the mononuclear fraction is isolated using a Ficoll-Hypaque density cushion. This fraction is plated into culture flasks to enrich for adherent cells. The nonadherent population is removed after approximately 7 days of incubation. The adherent cells are washed and detached by incubation with trypsin/ethylenediaminetetraacetic acid (EDTA) (alternatively, Trypzean, a recombinant form of trypsin, can be substituted) and then cultured and passaged at weekly intervals. In a study designed to optimize culture conditions, the best results were obtained when cells were cultured in low-glucose Dulbecco modified Eagle medium (DMEM)–based media containing 10% fetal bovine serum (human platelet lysate is now frequently substituted) and GlutaMAX instead of l-glutamine. The cells also proliferated better when plated at low cell densities (5000-10,000 cells/cm^2) in Falcon flasks. Use of basic fibroblast growth factor as a growth supplement was found to be effective; however, it caused HLA-DR induction and upregulated HLA class I expression. This did not affect the immunosuppressive capabilities of the cells. An increase in osteogenic and adipogenic potential was noted, but neurogenesis and engraftment support for CD34-positive cells were slightly suppressed. A number of media specifically designed for culture of MSC are commercially available (e.g., STEMPRO MSC-SFM a serum-free formulation from Invitrogen, and Mesencult, a basal culture medium from StemCell Technologies). Various investigators have reported success growing MSCs in serum-free media or using platelet lysate, autologous serum, or human AB serum as alternatives to fetal bovine serum.

Mesenchymal stromal cells can be characterized by their expression of CD105, CD73, and CD90 and their lack of expression of CD45, CD34, CD14 or CD11b, CD79a or CD19, and HLA-DR. They must be plastic adherent under standard culture conditions and must be capable of differentiating into osteoblasts, adipocytes, and chondroblasts in vitro. Differentiation assays involve growing MSCs under conditions that promote differentiation along the specific pathway. For neurogenic differentiation, the medium contains linoleic acid, platelet-derived growth factor, and epidermal growth factor. Neural cells are identified by immunostaining with antibodies against tubulin BIII, synaptophysin, galactocerebroside, neurofilament M, and neuronal nuclei (NeuN). To assess adipogenic potential, the medium contains dexamethasone, isobutylmethylxanthine, and indomethacin. The lipid droplets in the generated adipocytes are visualized by staining with Sudan black IV. Osteogenic differentiation is measured by culturing the cells in medium containing dexamethasone, β-glycerophosphate, and l-ascorbic acid 2-phosphate. Calcium accumulation and alkaline phosphatase activity in the resulting cells is visualized by alkaline phosphatase/Von Kossa staining, and the osteogenic differentiation is measured as the percentage of mineralized area in the total cultured area.

The ability of MSC to suppress an MLR is used as an indication of their immunosuppressive activity. A traditional MLR assay is used; however, in the test wells, the MLR is performed on a layer of MSC seeded the day before. The response traditionally is measured by uptake of tritiated thymidine. Numerous animal assays for MSC are available but are predominantly used in preclinical studies and are not useful as release assays. Release criteria consist of the usual assays for sterility, endotoxin, and mycoplasma, with immunophenotyping for the MSC population. Depending on the intended use of the MSC, the release process may require an assay showing potential for differentiation into a specific lineage or ability to suppress an immune response such as an MLR assay.

Genetically Modified Cell Therapy Products

Many cell therapy approaches involve genetic modification of either APCs or effector cells (see earlier discussion). This therapy requires a source of vector that has been manufactured to meet regulatory requirements. Vector specifications changed markedly after the death of a gene therapy patient in Philadelphia, and they continue to evolve. Manufacturers must maintain close contact with the FDA to ensure that their products meet current specifications. Manufacturing and testing of viral vectors is extremely expensive, and use of genetically modified products requires additional monitoring of recipients. Use of vectors to transduce or transfect cellular therapy products ex vivo usually requires additional testing of the product, which may include detection of replication competent virus and checking the functionality of the introduced vector (by detecting expression of the gene product).

Gene-Modified Tumor Vaccines

Tumor vaccines as an approach to inducing or stimulating immunity have been evaluated. Various techniques have been tested, including

use of DCs pulsed with a tumor-associated antigen preparation and use of the entire tumor cells as an immunogen, either unmodified or transduced with immunostimulatory genes, aimed at eliciting a broad-based, robust immune response.

From the manufacturing perspective, the autologous product is much more of a challenge because a stable tumor cell line must be isolated from each patient. This can be an extremely difficult process. Many isolated lines do not expand well in culture, or they change phenotype over time. In some patients, the line cannot be generated; other patients progress clinically before the vaccine is available and are excluded from the study. As a result, the autologous approach has a relatively high "failure rate." The allogeneic cell line approach is technically easier because a line is selected before the study and can be used as the generic immunogen. This line must be tested extensively for infectious agents and should pass the FDA testing criteria for Master and Working Cell Banks. Currently testing of this type costs $100,000 to $200,000 for each line. Scientifically, the drawback is that the selected line may not adequately express the antigen or range of antigens present on each patient's tumor. In addition, the choice of immunostimulatory molecules that are expressed or enhanced by transduction of the cell line may not be those that would most effectively evoke an immune response. These products are relatively expensive to produce, involving not only the costs of testing the tumor cell line but also the expense of manufacturing and testing the vectors used for transduction. However, these are one-time costs because the same vaccine is used for all patients in the study.

Release testing involves testing for sterility, endotoxin, and mycoplasma, with immunophenotyping of the cells and some form of test demonstrating that the line has been effectively transduced (e.g., flow cytometry for CD40 ligand and IL-2 production in the examples described earlier). Because the product will be stored cryopreserved over the course of the study and thawed for administration to each patient, the requirement for an ongoing stability study should be anticipated.

FUTURE DIRECTIONS

The science of hematopoietic transplantation has expanded dramatically over the past 10 years and has stimulated entirely new areas of medicine. New sources of stem cells have been discovered that have expanded the availability of grafts and provided new insights into stem cell biology. This in turn has stimulated the development of regenerative medicine to treat a wide variety of diseases for which there were limited therapeutic options. Time will provide insight as to the efficacy and mechanism of action of these approaches.

An improved understanding of immune responses and the effector cells involved has reinvigorated the field of immunotherapy and made it possible to design treatments that have a more realistic chance of success. Coupled with new laboratory techniques for the manipulation and selection of cells, these therapies are showing promise for the treatment of cancers and viral infections. Gene therapy is recovering from some early setbacks and disappointments to find a place in redirecting immune responses and retargeting cells.

These advances in knowledge coupled to development in technology promise a bright future for engineering specific cell populations to provide targeted therapies.

CHAPTER 99

PRINCIPLES OF CELL-BASED GENETIC THERAPIES

David A. Williams

The use of gene transfer to treat human diseases has now efficacious in a limited number of instances. Proof-of-principle successes proven in several monogenic diseases—both hematologic and nonhematologic—have been published and widely publicized in the past decade. Despite these successes, the occurrence of serious adverse events in some trials related to insertional mutagenesis has tempered the enthusiasm accompanying these reports but has also stimulated rapid development of safer vector systems. This chapter discusses the basic biology of vector systems applicable to blood diseases, discusses details of the application of gene therapy to blood diseases using specific trials as examples of this technology, and discusses modifications in vector systems driven by clinical experience that predict future trials. The chapter also discusses the prospects that the evolving field of somatic cell reprogramming may generate alternative cellular targets for genetic engineering.

HEMATOLOGIC DISEASES, CELLULAR TARGETS, AND THE BASIS FOR GENETIC THERAPIES

Gene therapy is defined as the introduction of new genetic material into the cells of an organism for therapeutic purposes. Broadly speaking, two types of gene therapy can be envisioned. The introduction of genetic material into germ cells such that the new DNA can be expected to be passed into the gene pool. This is termed *germline gene therapy* and is currently banned in the United States and around the world. In contrast, introduction of new genetic material into specialized cells of the body with no risk of the new genetic material being passed onto subsequent generations is termed *somatic gene therapy*. The ultimate goal of gene therapy would be to correct a genetic disease by *replacement* of the defective gene in situ. Such gene replacement could be envisioned via a process termed *homologous recombination*. Homologous recombination in mammalian cells is widely practiced in laboratories but up to now has been relatively inefficient. Advantages of this approach would include a reduction in the risk of inadvertent disruption or dysregulation of expression of a critical gene sequence and regulated (appropriate level and distribution) expression of the normal (replaced) gene. However, the frequency of this event (in contrast to random chromosomal integration) in mammalian cells makes therapeutic use of homologous recombination impractical at this point. Methods to effect homologous recombination have improved in the past 5 years and may make this goal attainable in the future.

The requirements for successful application of our current gene transfer technology for treatment of human diseases include knowledge of the abnormal gene sequence responsible for the disease phenotype and the availability of the corresponding normal gene sequence. In addition, the cells responsible for the disease phenotype must be identified and accessible for genetic manipulation. Finally, a means of introducing and expressing the correct gene sequence in cells such that the disease phenotype can be reversed is needed. This latter requirement has been, although effectively accomplished more than 2 decades ago in murine studies, the most difficult to consistently meet in human applications using current gene transfer technology. Since the early development of virus vectors, blood-forming cells have been used as one optimal target for gene transfer studies, and most studies to date use ex vivo approaches to genetic modification. For this purpose, hematopoietic stem and progenitor cells (HPSCs) are isolated, manipulated in the laboratory and administered back to the patient. The advantages of these cells as targets of gene transfer are multiple. First, all blood cells are derived from a common progenitor cell, the hematopoietic stem cell (HSC), which is both long lived in vivo and capable of significant self-renewal. The latter capacity and the pluripotency of HSC is exploited to amplify the genetically manipulated cells into large cell numbers of multiple blood lineages in vivo. There is a long and successful experience in obtaining these stem cells from the bone marrow (BM) and peripheral and umbilical cord blood. There is extensive experience in the use of HSCs in the clinical setting for transplantation, and there is experience in purification of these cells and limited knowledge of the requirements for ex vivo manipulation of the cells. In addition, the experience of HSC transplantation has defined a variety of genetic diseases in which the phenotype can be altered by the successful engraftment of normal allogeneic donor cells. Finally, the blood system is involved as a major dose-limiting organ in cancer therapies and both a target and an effector organ in immune reactions providing a large group of diseases that could theoretically be approached using gene transfer technology. As noted earlier, there are already a large number of monogenic diseases of the blood extensively characterized with more being defined at the molecular level on a regular basis because whole-exome and whole-genome sequencing is being applied to rare disease phenotypes. In addition to HSC targets, another application of gene transfer technology exploits the experience in adoptive T-cell immunotherapy. In this application, T cells (and less well developed to this point, other immune effector cells) are modified ex vivo in an attempt to enhance potency and specificity. This application of gene transfer technology will not be reviewed here.

The field of gene therapy is rapidly evolving. Successes of proof-of-principle small trials have demonstrated the utility of gene transfer approach in a sizable number of patients but in a limited number of diseases. The technology itself is quickly evolving in response to new understanding of viruses, the regulation of gene expression, and gene editing. The application of gene transfer technology to HSC gene therapy has been made possible by exploitation of viruses that have evolved the capacity to efficiently and precisely insert viral genome into cellular chromosomes of infected cells. The field has taken about 25 years to evolve to its current state of clinical application. Although this might be viewed as a slow pace, in reality, this time frame parallels the development of many other novel therapies. This developmental phase also reflects the complexities of the biologic systems involved and the caution required in moving forward in the face of serious adverse events seen in early safety trials. It is indeed an exciting time with respect to the clinical application of gene transfer technology in human diseases.

VECTOR SYSTEMS

The initial impetus to develop gene transfer for human studies derived from the exploitation of oncoretroviruses, mainly murine γ-retroviruses, as vectors for gene delivery in the early 1980s.[1a]

However, over approximately the past 25 years, a multitude of virus vectors have been developed. All vector systems use parts of the virus life cycle in an attempt to increase the frequency and fidelity of gene transfer. Although many vector systems have been developed, retrovirus vectors remain the most used system for human gene therapy trials involving HSC, and this review will focus primarily on this vector system and the closely related lentivirus, foamy virus, and avian virus vectors (reviewed by Touw and Erkeland[1b]). As noted, the majority of trials registered with the Recombinant DNA Advisory Committee (RAC) of the National Institutes of Health use retroviruses with non-integrating adenovirus vectors, adeno-associated virus and nonvirus (liposomes and plasmids) systems making up the second and third largest groups.[2] The latter are primarily focused on immune stimulation trials in cancer and have limited relevance to the use of HPSCs for the treatment of genetic blood diseases.

Retrovirus Vectors

The use of γ-retroviruses as gene transfer vectors takes advantage of the normal virus life cycle. The virus, a membrane-bound particle enclosing a dimer of genomic RNA, gag, and reverse transcriptase proteins, interacts with specific cell surface receptors on the target cell. After entry into the cytoplasm, the virus is uncoated, and the genomic messenger (m) RNA is reverse transcribed into DNA. Subsequent polymerase activity yields a double-stranded (DS) DNA provirus molecule. For γ-retroviruses, transport into the nucleus depends on the loss of the nuclear membrane, which accompanies cell division (see later discussion). Integration of the DS provirus is semirandom in the chromosome, which allows tracking of subsequent progeny cells using molecular analysis of unique integration junctional fragments. The occurrence of insertional activation of oncogenes in several human trials and the subsequent scrutiny of insertion sites in HSC-derived progeny in both murine and human cells using deep sequencing methods have provided a more detailed understanding of subtle but biologically relevant preferences for insertions of these vectors (see later discussion). After being integrated, the provirus can give rise to mRNA leading to encoded protein products. Full-length (genomic) mRNA can also be used as the genomic nucleic acid in newly formed virus particles, which are budded nonlytically from the cell surface after assembly in the cytoplasm of the infected cell. Use of retroviruses for gene delivery depends on the capacity to replace viral genes with other heterologous gene sequences and to provide necessary viral proteins in trans in specialized cell lines, called *packaging cells*. The advanced generation of packaging cells appears to be capable of generating pure stocks of recombinant virus without contaminating wild-type helper virus, an important safety consideration. Indeed, to date in human trials, there have been no reports of inadvertent generation of infectious virus. Thus, this infection with replication-incompetent (ie helper-free) retrovirus vectors would be predicted to yield integration into the targeted cell population but no further spread of virus in the body of the treated patient. The proteins provided in trans for γ-retroviruses are generally gag, reverse transcriptase, and envelope proteins, the latter defining the host range of infection. In summary, the advantages of retrovirus vectors include the high efficiency of stable transfer of intact DNA sequences, the broad range of host cells susceptible to infection by retroviruses, and the ability to generate helper-free recombinant virus.

Despite these advantages, the application of retrovirus vectors to treatment of human blood diseases in early trials was disappointing. In multiple studies, transduction of long-lived and transplantable HSCs has been extremely low. In most studies, the frequency of circulating marked blood cells was too low to effect phenotypic correction of any disease, usually less than 0.1%. The biologic parameters contributing to the poor results in human trials are varied. The major impediments appear to include the low levels of viral receptors on the surface of human HSCs, reducing the efficiency of interaction of virus particles with these target cells,[3-5] and the quiescent nature of the majority of HSC, which hinders the transport of the provirus into the nucleus and thus reduces integration frequency. Practical issues, including the difficulty in obtaining high-titer virus in large-scale preparations required for human trials, have also been noted.

These difficulties have led to various strategies and development of entirely new vector systems, which seek to improve gene transfer methods in human HSCs. These strategies include attempts to increase virus–cell interactions or methods to enhance the chances of successful DNA integration. Different viral envelopes were used to pseudotype recombinant particles to more efficiently target CD34 cells.[6-10] The use of various cell surface markers, such as CD34, to purify the target cell population can also increase the multiplicity of infection at a given virus titer and has been used in clinical transplantation protocols. Thus, the development of antibody-based enrichment of the $CD34^+$ HPSC compartment from human hematopoietic tissues using magnetic column purification provided a rapid, clinically applicable method to further enhance retroviral transduction by increasing the vector to target cell ratio.[11-14] Methods to increase physical interactions between vector particles and target cells include co-localization on fibronectin and centrifugation methods. Where polycations such as polybrene had previously been used to enhance transduction frequencies by negating electrostatic charge repulsion between target cells and viral particles, the characterization of the recombinant CH296 fibronectin fragment (Retronectin has a matrix upon which one could co-localize HSCs and viral particles was a significant advance in the quest to improve $CD34^+$ transduction frequencies.[15-18] Efforts to increase the chances of DNA integration have focused on attempts to increase the number of HSC that are undergoing cell division (primarily the use of cytokines that effect stem cell proliferation). The development of improved in vitro growth media formulations incorporating novel cytokine cocktails achieved the dual aim of promoting HSC division, which is required for transduction with gammaretroviral vectors while minimizing stem cell loss in vitro via apoptosis or differentiation.[19-25] Finally, the use of new virus systems that do not require nuclear membrane disruption (and therefore cell division) for entry of the provirus DNA into the nucleus, including primarily lentivirus vectors but potentially also vectors based on foamy viruses, appears to be the most significant development in the field in the past decade. These newer vector systems will be discussed later.

In addition to the energy in the field that was devoted to advancing stem cell transduction methodology, additional work focused on developing retroviral vectors that would express transgene cassettes at levels that would be high enough to elicit a therapeutic benefit and be resistant to gene silencing. Advances in vector design such as the optimization of long-terminal repeat (LTR) enhancer and promoter elements and viral leader sequences resulted in recombinant vectors that were able to mediate high level transgene expression in both primitive and mature hematopoietic cells.[26-32] As discussed in detail later, although these power promoter and enhancer elements provided robust expression of transgenes, they appear also to be capable of long-range activation of endogenous regulatory sequences as a form of insertional mutagenesis that can have significant deleterious effects. Taken together, these technologic advances served as the platform for the first successful gene therapy trial in humans.

The use of pharmacologic in vivo selection in combination with gene transfer, both in the setting of cancer trials and in genetic diseases, remains a potentially important method to enhance the reconstitution of human recipients with gene-modified blood cells but has not yet gained widespread usage. This approach is reviewed in more detail in a recent publication.[33] General considerations include the need for a particular drug to effect damage to BM stem or progenitor cells. A gene or genes encoding resistance to this agent would need to be identified and resistance in vivo to the agent would need to be demonstrated after overexpression of this gene in BM cells. For applications in cancer therapies, dose intensification of drugs used within chemotherapeutic regimens should improve antitumor efficacy. For noncancer applications (most likely uses attempting co-selection of a nonselectable therapeutic gene in a genetic disease application), the mutagenic potential of the chemotherapy agent must be considered as a risk in relation to the overall benefit of the gene therapy

procedure. Several chemoresistance genes and chemotherapy drug combinations are currently under investigation for this application, and encouraging preclinical studies have led to a limited number of early phase human studies in cancer patients.

Lentivirus Vectors

One of the key advances in the gene therapy field in the past decade has been the development of recombinant vectors based on lentiviruses, including human immunodeficiency virus (HIV). These vectors were originally developed after the observation that targets of HIV included more differentiated cells, such as macrophages, that are often also postmitotic, suggesting this group of retroviruses has evolved a method of circumventing the block in infection of gammaretroviruses seen in nondividing cells. Investigators demonstrated lentivirus vectors derived from HIV were capable of infecting nondividing neurons after direct injection into the brain.[34] Subsequently, Naldini et al[35] showed efficient infection of growth arrested cells. As with gammaretroviruses, lentivirus vectors use key viral gene products in trans to generate replication-defective infectious particles carrying the transgene of interest. To date, most lentivirus vectors use vesicular stomatitis virus as envelope sequence, which provides a very broad range of target cells susceptible to lentivirus vector transduction. In the case of lentivirus vectors, viral gag and pol as well as tat and rev proteins expression are required in trans for efficient virus production along with the envelope proteins. These proteins are usually supplied from separate plasmids, and recombinant lentivirus production is today generally created using "four plasmid" systems encompassing all the necessary viral proteins on three plasmids and the transfer vector sequences on the fourth plasmid.[36] In addition to *gag* and *pol,* the transfer vector contains all the virus regulatory sequences required *in cis* for packaging an infectious particle, including the *psi* packaging sequence, integrase, and reverse transcriptase. Thus, generation of high-titer recombinant virus is more complicated than gammaretroviruses.

To reduce the chances of generation of replication competent retroviruses (RCRs), a major safety concern with HIV, most of the nonessential viral sequences were removed from vectors. This included *viv, vpu, vpr,* and *nef* genes and subsequently *tat,* an important regulator of viral transcription. Recombinant vectors generated without these sequences were demonstrated to efficiently infect a variety of cells.[36,37] RCR testing is based on sensitive assays to detect gag protein by p24 immunoassays or polymerase chain reaction. In addition, lentivirus vectors have traditionally been produced using the "self-inactivating design" (SIN) for added safety because of reduced risk of recombination with and subsequent mobilization of endogenous HIV viruses. The transfer vector thus contains a deletion of the 5′ LTR U3 region and are devoid of viral enhancer and promoter sequences. During reverse transcription, the 5′ LTR is replicated, and the integrated provirus is thus devoid of both 5′ and 3′ U3 regions.[38,39] In SIN constructs, the transgene of interest is thus expressed from an internal promoter that can be chosen with varying strengths. This added safety feature ultimately has proven important also to reduce the risk of insertional mutagenesis (see later) by which integration near cellular genes are inadvertently activated by the LTR enhancer sequences of vectors.

Lentivirus vectors were originally developed for use in a wide range of tissues in which cells are largely nondividing. Early work focused on brain,[35,40] retinal cells,[39] liver,[41] pancreatic islets,[42] airway epithelium,[43] and muscle.[41,44] However, it was subsequently appreciated that the requirement of stimulating HSCs into division with various cytokines to effect efficient transduction with gammaretrovirus vectors may have negative effects on engraftment or that a large fraction of HSCs remain quiescent and therefore resistant to transduction during clinical transduction protocols. After several groups reported successful transduction of primitive HSC populations in protocols in which these cells remained resistant to transduction by gammaretroviruses,[45-49] the adaption of lentivirus vectors has now included several recent human trials, and initial results are encouraging. In a trial for adrenoleukodystrophy, long-term "marking" in the myeloid compartment appears to be 10% to 20%, a level that is about 100-fold higher than the marking in the myeloid compartment seen in previous trials in immunodeficiency conditions that used gammaretrovirus vectors.[50] In addition to the safety advantage of SIN vector design used in all lentivirus vectors, there is an additional theoretical advantage of the preference of lentiviruses for integration away from transcription start sites (TSS) of genes in contrast to gammaretroviruses. However, the recent experience with a lentivirus vector used in a single patient with thalassemia,[51] in which abnormal splicing resulted in clonal expansion in the erythroid compartment, suggests that insertion within genes may also have potential adverse effects on endogenous sequences. These trials are described in more detail later. Thus, long-term safety of lentiviruses in human trials remains to be determined, and important aspects of insertional mutagenesis are described in more detail later.

Foamy Virus Vectors

Foamy viruses possess several features that have been exploited to yield vectors for the purpose of transducing HSCs.[52] Foamy viruses are members of the spumaretroviruses family. They have been shown to be endemic retroviruses in a wide range of animals but are not found in humans. These vectors are the largest of the retroviruses (≈14 kb) and thus yield vectors with a capacity to efficiently package large amounts of genetic sequences.[53] The virus has a DNA genome that is reversed transcribed within the virion particle forming a stable preintegration complex within the transduced cell. As with gammaretrovirus vectors, the virus packaging signals have been successfully exploited to allow production of high-titer, replication-free vector stocks.[54] Based on accidental exposure of a limited number of animal care workers, it has been reported that infection of humans with wild-type foamy virus has no pathologic effects.[55] Foamy virus vectors have been used to successfully transduce mouse and human hematopoietic cells. Proof-of-principle work by Hickstein's group has demonstrated correction of canine leukocyte adhesion deficiency using a foamy virus vector expressing CD18 after transduction and infusion of $CD34^+$ cells after submyeloablative conditioning.[56] No human trials have been opened to date using this vector system, but several are planned for the future.

Alpharetroviruses

Retrovirus vectors derived from Rous sarcoma virus, which is a member of the alpharetrovirus family, have been described. Although these vectors maintain genomic integration as part of the viral life cycle, they have attracted recent attention because of their propensity to integrate in a relatively neutral fashion with respect to promoter regions and TSS of genes.[57] In large animal studies, alpharetrovirus-transduced HSC-derived progeny demonstrated integrations that were not clustered in gene-rich CpG or TSS regions of the genome.[58,59] The development of a self-inactivating alpharetrovirus with a split-packaging design by Schambach and colleagues has provided proof-of-principle with respect to the capacity to generate high-titer, replication-free vector stocks that use internal promoters to express transgenes in a potentially safer fashion than gammaretrovirus vectors.[60] Such vectors have been demonstrated to efficiently infect murine and human hematopoietic cells at low multiplicity of infection.[60]

EXPERIENCE IN HEMATOLOGIC CLINICAL TRIALS TO DATE

X-Linked Severe Combined Immunodeficiency

Severe combined immunodeficiency (SCID) comprises a number of rare monogenic diseases with the common feature of a block in T-cell differentiation and impaired B-cell and natural killer (NK) cell

immunity.[61] Studies of pattern of inheritance, immune function, and genotypes have led to the identification of at least 11 distinct SCID conditions. The most common variant of SCID results from the deficiency in expression or function of the common cytokine receptor γ chain, which is shared by the receptors for interleukin (IL)-2, IL-4, IL-7, IL-9, IL-15, and IL-21. This condition is inherited in a sex-linked fashion (X-linked SCID or SCID-X1) and accounts for 40% to 50% of all SCID cases.[62,63] SCID-X1 is characterized by abnormal development or function of T, B, and NK cells, although B cells are usually present in humans (so called T-minus, B-plus SCID). Survival depends on the reconstitution of T-cell development and function by allogeneic BM transplantation.[64,65] If a genotypically matched family donor is available, HSC transplantation (HSCT) confers greater than 80% chance of long-term survival.[65] The absence of T and NK cells in the patient allows for the engraftment of donor cells without preparative chemotherapy conditioning; thus, this is the treatment of choice with minimal toxicity. When a genotypically matched family member is not available, haploidentical donors (e.g., a parent) or closely matched unrelated donors are used, with varying preference center to center, and a survival rate of 64% to 78% has been reported.[64-68] These inferior outcomes may be attributed to the increased risk of graft rejection or graft-versus-host disease (GVHD), as well as the effects of T-cell depletion, immune suppression causing slower immune reconstitution, or conditioning with increased risk of infection.[69,70] Haploidentical transplants rigorously depleted of T cells, similar to genotypically related transplant, are performed in some institutions without preparative chemotherapy conditioning; however, B-cell reconstitution is poor, and the majority of patients require intravenous immunoglobulin (IVIG) replacement for life.[69,70] Interestingly, spontaneous partial correction of severe T-cell immunodeficiencies, including SCID, has previously been reported, suggesting a selective advantage of wild-type T cells over defective T cells.[71-73]

Two independent gene therapy trials aimed at correcting the immunologic defect of SCID-X1 patients who lack a genotypically matched BM donor have been reported,[74,75] and another has recently been opened for accrual. Thus far, a total of 20 patients have been treated in the reported studies. Despite minor technical differences in the two protocols, the basic design of both gene therapy trials is quite similar: The complete coding region of the human γ chain was cloned into a "first-generation" gammaretroviral vector regulated by the murine leukemia virus (MLV) LTR sequences, which was used to infect BM-derived $CD34^+$ cells in vitro. The transduction occurred in the presence of early acting cytokines (stem cell factor, thrombopoietin, IL-3, and FMS-like tyrosine kinase 3 [FLT 3] ligand) and the CH296 human fragment of fibronectin described earlier. Cells were subsequently infused without prior conditioning or cytoreductive treatment. Minor differences between the two protocols included the uses of a threefold higher concentration of IL-3 and 4% fetal cell serum in the French trial. Additionally, the French investigators used the amphotropic envelope pseudotype compared with the use of gibbon ape leukemia virus (GALV) envelope in the British trial.[74,75] Results in both trials have been extremely encouraging.

In the French trial, 10 children younger than the age of 1 year were enrolled between 1999 and 2002.[74,76] Nine of 10 infants developed normal numbers of T and NK cells, with good immune function.[77] In seven of the nine patients who developed T cells, T-cell counts reached normal levels within 3 months and have remained normal at the time of the last published follow-up.[78] Protective levels of antibodies, including antibody production after immunization, were achieved, and the prophylactic administration of IVIG was discontinued.[77] At almost 8 years after gene therapy, these patients continued to retain a functional immune system, enabling them to live normally.[78]

However, serious adverse events related to gene therapy have been reported in four patients in the French trial, occurring 31 to 68 months after gene therapy,[78-80] and in one patient in the British trial.[75,81] In these patients, untoward effects of viral integration into the genome resulted in T-cell leukemia, leading to the death of one of the four affected patients. Much research has subsequently been directed at elucidating the mechanism responsible for these adverse events. Retroviral integration in the proximity of proto-oncogenes, particularly the LIM domain only 2 (LMO2) promoter, was involved in leukemogenesis in three French patients and one British patient.[78,81] An integration of the unaltered γ chain–encoding viral vector on chromosome 11q13, near the first exon of the *LMO2* gene, led to the unregulated transcription of LMO2, giving rise to a T-cell acute lymphoblastic leukemia (T-ALL)–like lymphoproliferation in the initial two patients.[79] In the patient in the British trial, the integration of the vector 35 kb upstream of the *LMO2* locus cooperated with secondary genetic aberrations, including a gain of function mutation of NOTCH1, a deletion at the CDKN2A tumor suppressor gene locus, and a translocation of the T-cell receptor β region, to give rise to T-ALL.[81] LMO2 is a master regulator of human hematopoiesis that is involved in stem cell growth and is not normally expressed in T cells. However, LMO2 activation has been has been implicated in some cases of human T-cell leukemia.[82] In addition, LMO2 transgenic mice have been shown to develop T-ALL within 10 months.[83] It is increasingly clear that retroviral vectors may "turn on" cellular proto-oncogenes adjacent to their integration site in the genome. The strong promoter or enhancer activity of the retroviral LTR element shows particular propensity to the upregulation of genes neighboring the integration site.[84-86] Multiple studies now indicate that gammaretroviral vectors, such as the vectors used in the two SCID-X1 trials, preferentially integrate into the 5′ end of genes near the TSS.[87] In addition, gammaretroviral vectors have been shown to integrate in or near a number of proto-oncogenes that are actively expressed in human $CD34^+$ cells. When human $CD34^+$ cells were transduced with retroviral vectors ex vivo, 21% of retroviral integrations occurred at recurrent insertion sites ("hot spots"), which were highly enriched for proto-oncogenes and growth-controlling genes.[88] A recent series of papers investigating the vector integration sites in both SCID-X1 trials and the Italian Adenosine Deaminase Deficiency SCID trial observed a greater than random frequency of vector integrations near the TSS of genes that are active in HSCs.[89-91] Interestingly, in the SCID-X1 trial, a skewing of vector integration site distribution in vivo was noted. Compared with retroviral integration sites (RIS) recovered from transduced $CD34^+$ cells, RIS recovered from T cells in vivo 9 to 30 months after transplantation showed an overrepresentation of RIS within or near genes encoding proteins with kinase activity, transferase activity, or proteins involved in phosphorous metabolism. This skewing of RIS in vivo suggests a selection of T cells as a result of viral integration in certain growth- and survival-promoting genes.[89]

Strikingly, in contrast to five cases of insertional mutagenesis in the two SCID-X1 trials, no adverse events have been reported in the 10 patients treated in the Italian ADA-SCID trial despite a similar RIS pattern observed in this patient group.[90] This observation has led to the proposal of a "disease effect" contributing to oncogenesis of γ-chain gene therapy. Woods et al[92] demonstrated lentiviral transduction of $\gamma c^{-/-}$ mice with vectors containing the human common γ chain (cγ) or an inert control gene at very high viral doses. They observed the induction of T-cell malignancies in one-third of the animals receiving cγ transduced cells but not in the control groups. The merit of this very limited study was subsequently challenged, primarily on the basis of a viral dose much higher than that used in clinical scenarios and incomplete data on the pathogenesis of the malignancies, particularly as they relate to the downstream activation level of a key signaling target of the common γ chain, Janus kinase 3 (JAK3), in the tumors.[93,94] In addition, the lentiviral vector used in this study incorporated a hybrid promoter or enhancer element that is extremely powerful and likely to possess a greater transactivating potential than promoter or enhancer elements that would be considered for clinical gene therapy use.[92] More recent occurrence of leukemia in another trial for Wiskcott-Aldrich Syndrome (WAS; see later) using the same vector backbone further challenges the presence of SCID-X1 disease or transgene effects in these leukemias.

In summary, thus far, 5 of 20 patients treated with gene therapy for SCID-X1 have encountered a life-threatening severe adverse event, thought to be triggered by retroviral activation of LMO2 in 4 patients. Four patients were salvaged with chemotherapy, and one

patient succumbed to the disease after an unsuccessful allogeneic BM transplantation (BMT). At this point, the use of MLV-based retroviral vectors with LTR promoter enhancer elements intact is viewed as contraindicated in this disease by most investigators in the field. The continued development of safety-enhanced vectors and the validation of these vectors in clinically relevant systems have emerged as a major priority in the field, and an international trial has recently been opened using a gammaretrovirus that is deleted of LTR enhancer elements. Transgene expression is mediated by a weak cellular promoter in this vector. Data suggest that early efficacy is maintained despite lower expression of the IL-2 γ chain.[95]

Adenosine Deaminase Deficiency

Adenosine deaminase (ADA) is a housekeeping enzyme of the purine metabolic pathway that is expressed in all tissues of the body.[96] Deficiency of this enzyme leads to a buildup of toxic metabolites with detrimental systemic effects, including neurodevelopmental deficiencies, sensorineuronal deafness, and skeletal abnormalities. Importantly, ADA deficiency causes abnormal T-, B-, and NK-cell development, resulting in the SCID phenotype. As is the case with the more common SCID-X1, untreated patients generally succumb to severe opportunistic infections in the first year of life. Treatment strategies used to manage affected patients include allogeneic HSCT; enzyme replacement therapy; and more recently, gene therapy.[97] Allogeneic HSCT from a human leukocyte antigen (HLA)–matched family donor offers good immunologic and biochemical correction with 73% survival. However, outcomes after mismatched and haploidentical transplants are less impressive.[65] Likewise, the exogenous replacement of ADA, administered in a polyethylene glycol (PEG) conjugate by intramuscular injection on a weekly or twice-weekly schedule, results in systemic detoxification and immune reconstitution. In the long term, however, about half of the patients receiving PEG-ADA replacement continue to require IVIG infusions, and some patients show a decline in T-cell numbers over time.

A number of gene therapy trials for ADA deficiency were initiated in the early 1990s, targeting retroviral gene transfer into various cell types, including peripheral blood lymphocytes, umbilical cord blood, BM, and $CD34^+$ selected stem cells.[98-101] These early studies failed to produce clear efficacy. By contrast, more recent studies introduced key modifications to the gene therapy protocol, including the use of a reduced-intensity myelosuppressive conditioning regimen and the withdrawal of concurrent PEG-ADA replacement.[102,103] The Milan-based group of Aiuti and colleagues have reported on their initial experience with 10 children.[90] Patients were conditioned with 4 mg/kg of busulfan before the infusion of transduced cells. The mean age at the time of gene therapy was 2.2 years. All children on this trial are healthy and thriving, with the longest published follow-up time now more than 64 months.[90,97,104] Gene therapy has resulted in a substantial increase of lymphocyte counts and normalization of T-cell function.

Similarly, four patients have been treated in London.[105] One patient that has been reported in detail had been treated with PEG-ADA for 3 years but showed a gradual decline in T-cell numbers despite effective metabolic correction. Because a matched BM donor was not available, the patient was enrolled on the ADA-SCID gene therapy trial. PEG-ADA replacement was stopped 1 month before gene therapy, and the patient was conditioned with a single dose of 140 mg/m^2 of melphalan before the infusion of the transduced BM $CD34^+$ cells.[103] At the time of the last published follow-up, the patient was 2 years from gene therapy, clinically well, and off prophylactic antibiotic therapy. An increase in T-cell numbers and normalization of the proliferative response have been noted.[97,103] Importantly, no adverse events have occurred thus far in the patients treated for ADA-SCID at these two centers.

Aiuti et al[90] recently published a comprehensive genome-wide analysis of RIS of five patients treated in Milan. This paper analyzed the RIS patterns in $CD34^+$ cells before infusion as well as RIS in vivo, up to 47 months after gene therapy. As anticipated, a nonrandom proviral integration pattern, favoring TSS and gene dense regions, was observed in the pretransplant cells. RIS observed in vivo in T cells were additionally enriched for TSS, suggesting the occurrence of in vivo selection. More recently, Aiuti and colleagues[104] have demonstrated that cellular genes in the proximity of the proviral integration site are subject to moderate dysregulation in gene modified T-cell clones isolated from patients. However, in contrast to the SCID-X1 trial, no in vivo skewing toward RIS in genes affecting survival, cell cycling, signal transduction, or proliferation were observed, making a clonal dominance effect appear less likely. Interestingly, only one *RIS* was detected at the MDS-EVI1 locus and became undetectable at later time points. This is in contrast to the clonal dominance of *MDS-EVI1* integration sites observed in the X-linked Chronic Granulomatous Disease trial[107] (see later). Additionally, an overrepresentation of RIS was noted in the proximity of the *CCND2* and *LMO2* gene with a total of 5 of 523 RIS recovered in vivo. Notably, the *CCND2* insertions were detected only in the first 2 years of follow-up and not subsequently. *LMO2* insertions were also overrepresented in the pretransplant $CD34^+$ samples, highlighting the fact that the *LMO2* gene is a hot spot for retroviral integration in human $CD34^+$ cells.[90] The lack of in vivo expansion of clones carrying LMO2 RIS indicates that this integration site may not be sufficient to mediate clonal dominance and leukemic transformation. Rather, additional cooperating mutations or insertions are required for malignant transformation. The lack of malignant transformation in two ADA-SCID trials may point to the role of the genetic background or the role of the therapeutic transgene introduced into human $CD34^+$ cells. However, the patient cohort remains relatively small, and follow-up is still short term. Overall, the genotoxicity profile in these two ADA-SCID trials has been sufficiently favorable to continue to recommend this experimental therapy to patients and families lacking a perfectly matched sibling donor. Indeed, this vector and treatment portfolio has been licensed in 2011 to a major pharmaceutical company for clinical development.

Chronic Granulomatous Disease

Chronic granulomatous disease (CGD) is an inherited disorder of phagocyte dysfunction characterized by often life-threatening invasive fungal and bacterial infections and by granuloma formation in vital organs. CGD results from a mutation in one of four subunits of the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase of phagocytes. The inability to form microbiocidal oxygen species renders the phagocytes unable to fight invasive infections.[108] Almost 70% of CGD cases result from defects in the X-linked gene encoding $gp91^{phox}$ (X-CGD). With conventional therapy, including lifelong antimicrobial prophylaxis and interferon-γ therapy, the yearly mortality rate of X-CGD remains at 5%.[109] BMT is curative for patients with a perfectly matched sibling donor but remains risky in patients with active infections. Unrelated donor transplantations are not routinely recommended.[110] Thus, the development of a gene therapy approach that uses autologous HSC provides an important therapeutic advance for this patient group. In previous clinical gene therapy trials conducted without myeloreductive conditioning, the engraftment level of gene modified cells remained low.[111]

In 2002, the German group of Grez and colleagues in Frankfurt, Germany, initiated a gene therapy trial of X-CGD. The initial patients received a mild immunosuppressive preparative regimen and failed to engraft significant numbers of gene modified cells. However, 2 years later, low-dose busulfan—modeled on the successful gene therapy trial for ADA-SCID[102]—was incorporated into the preparative regimen, and additional patients were treated.[107] This group of patients has been followed with unprecedented sophistication by the prospective monitoring of integration sites that marks each hematopoietic cell before transplantation and then allows the tracking of these cells in vivo.[107] The initial two patients treated were 26 and 25 years old. Both subjects carried the diagnosis of X-CGD and had failed to clear invasive infections, including a *Staphylococcus aureus*

liver abscess and pulmonary aspergillosis with medical treatment. Thus, autologous peripheral blood $CD34^+$ cells were mobilized with granulocyte colony-stimulating factor (G-CSF) and collected. Gene transfer was performed using a gammaretroviral vector $SF71gp91^{phox}$. This vector, containing the spleen focus-forming virus LTR elements (in contrast to the Moloney MLV LTR in the two SCID trials) was chosen for its ability to achieve high expression levels in transduced HSCs.[112] The in vitro transduction rates in the two patients were 45% and 39.5%, respectively, with a proviral copy number of 2.6 and 1.5 per transduced cell. Proviral integration occurred preferentially in gene-coding regions (47%-52%) and was highly skewed toward the 5-kb sequence surrounding TSS. Moreover, the clonal distribution pattern was not stable over time. Rather, starting 5 months after therapy, a less diverse integration pattern emerged, indicating the appearance of dominant clones.

Clinically, following a period of cytopenia after the conditioning and cell infusion, the initial engraftment rates detected in the peripheral blood were 12% to 13%. Significant improvement in the previously refractory infections was noted 50 to 60 days after therapy. Surprisingly, a gradual increase in the number of gene-corrected cells up to 50% to 60% of all peripheral blood cells was observed, starting around day 150 after transplant. This coincided with increased oxidase activity and occurred in the absence of altered blood counts. These events were accompanied by a selective outgrowth of progenitors carrying vector insertions that activated one of three oncogenes, *PRDM16, SETBP1,* and most notably *MDS-EVI1.* Although all three genes are well-known cancer-associated genes, most clonal outgrowths were exhausted after a few months with the exception of *MDS-EVI1,* which increased to 67% to 90% in both patients approximately 1 year after cell infusion. Of note, the dominant *MDS-EVI1* clones initially did not transgress the boundaries of the normal myeloid pool because these cells remained cytokine dependent in vitro and failed to engraft in immunocompromised mice, suggesting their benign nature.[107] Thus, the expansion of $gp91^{phox+}$ cells, although clearly providing therapeutic benefit during the initial phase, was viewed with mixed feelings by the investigators and the general gene therapy community.

More recent follow-up on these two study patients has been provided.[113,114] Indeed, although gene marking remained high in both patients, downregulation of gene expression was noted as a result of CpG methylation in the viral LTR promoter. As a consequence, $gp91^{phox}$ expression was suppressed, but the capacity of the LTR encoded enhancer to transactivate nearby genes remained intact.[115] One patient died 2.5 years after therapy of severe sepsis.[116] The second patient developed monosomy 7 and myelodysplastic syndrome (MDS) and died after an unsuccessful unrelated donor BMT.[113] Of note, the *EVI1* locus has previously been identified as a common target of retroviral oncogenesis.[84,117] EVI1, which is not detected in normal hematopoietic cells, has been associated with myeloid leukemia and MDS.[118,119] The constitutive overexpression of Evi1 in mouse BM cells has been shown to induce MDS in mice,[120] and data from the CGD trial suggest that dysregulated expression is associated with genomic instability, presumably contributing to the acquisition of additional somatic mutations. Despite these molecular events, the infusion of gene-corrected $CD34^+$ cells was highly effective with regard to clearing refractory pyogenic infections,[107] raising the possibility of using gene therapy to bridge patients with refractory pyogenic infections into eligibility for allogeneic HSCT.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome (WAS) is an X-linked immunodeficiency caused by inactivating mutations in the WAS protein (WASP). WASP plays a regulatory role in cell signaling and cytoskeletal reorganization in hematopoietic cells.[121] The disease is fatal and is characterized by severe combined immunodeficiency, thrombocytopenia, elevated frequency of tumor formation, eczema, and other autoimmune manifestations.[122] The only currently available curative therapy for WAS is BM transplant, but as with the other primary immunodeficiencies, the availability of suitably matched donors is limiting.[123] A clinical trial for the genetic correction of WAS via retroviral delivery of the WASP cDNA into autologous $CD34^+$ cells was recently reported.[124a] A combination of a relatively high cell dose ($8\text{-}7 \times 10^6$ $CD34^+$/kg body weight) and good transduction efficiency led to gene marking across both myeloid and lymphoid lineages. A marked clinical benefit from gene therapy has been reported in one of the patients.[124a] Of particular note is the fact that the architecture of the vector backbone used in this trial is similar to that used in both the CGD and the SCID trials described earlier. That is, the gammaretroviral vector has an intact LTR that contains the enhancer and promoter from the spleen focus forming virus.[124b] Recent reports describe T-cell leukemia from insertional mutagenesis in four patients in this trial (C. Klein, personal communication). Thus, a common molecular etiology in this trial strongly suggests that the initial vector design (intact strong viral LTRs containing enhancer elements that can transactivate promoters over long distances) are unsafe. In addition, the occurrence of T-cell leukemia in a disease other than SCID weakens the argument that the leukemias in X-SCID was related either to the transgene or some unknown disease-specific characteristic. In any regard, use of the "first–generation" MLV backbone in human trials may now be ended.

Childhood Cerebral X-Linked Adrenoleukodystrophy

Childhood cerebral X-linked adrenoleukodystrophy (CCALD) is a fatal neurodegenerative disease that results from progressive neural demyelination within the brain.[125,126] The defective gene that is responsible for the phenotype, adenosine triphosphate–binding cassette D1 (ABCD1), encodes a transmembrane transport protein that is responsible for the shuttling of fatty acids into peroxisomes, where they are subsequently degraded.[127] ALD is characterized by an accumulation of very long chain fatty acids, although the exact pathophysiology of the disease is unknown. Cerebral demyelination is associated with inflammation evident on gadolinium magnetic resonance imaging studies. Most patients progress from no symptoms to a vegetative state and death within 5 years of diagnosis. Allogeneic BM transplant has been found to be therapeutic for cerebral demyelination, presumably because of the infiltration of donor-derived microglia cells into the brain.[128] However, because of the very rapidly progressive nature of the demyelination and the time required to generate mature microglia from transplanted HSCs, BM transplant is most effective when administered as soon after development of demyelination evident by imaging methods as possible.[128] In cases in which CCALD is successfully treated with HSCT, continued progression of the disease occurs for 18 months to 2 years before disease arrest. Myelin inflammation resolves, but lost neurologic function is not regained in successfully treated patients. Because of the time constraints imposed upon finding a suitable HLA-matched donor and the occurrence of GVHD, the genetic correction of autologous BM $CD34^+$ cells is an attractive experimental therapeutic option.

A phase 1 gene therapy trial using a recombinant HIV-1 based lentiviral vector to deliver the ABCD1 cDNA into $CD34^+$ cells has been reported from Paris.[50] In the three patients who have been enrolled to date, a transduction efficiency of 30% to 50% in $CD34^+$ cells was achieved with mean vector copy numbers of 0.6 to 0.7 per cell. Patients were preconditioned with cyclophosphamide and busulfan, and between 9% and 23% multilineage gene marked chimerism has been reported in a follow-up period that extends up to 16 months. In the two patients who have been followed for 16 months after transplant, HSC gene therapy resulted in arrests of neurologic functional loss and resolution of central nervous system inflammation that are similar to those achieved with allogeneic transplant. This trial is particularly noteworthy in that it is the first trial to report reconstitution of BM cells that have been transduced with a recombinant lentiviral vector. Molecular characterization of lentiviral integration sites in engrafting cells indicated that reconstitution was polyclonal, but detailed analysis of genomic loci targeted by this vector has yet

to be reported. A multisite, biotechnology-sponsored registration trial is currently being reviewed by regulators in several countries using a similar lentivirus vector in this disease.

β-Thalassemia

A second patient treated in a clinical trial that used a lentiviral vector has recently been reported for the correction of β-thalassemia.[51] Thalassemias result from mutations that attenuate the expression of either the α or β globin chains that compromises hemoglobin synthesis and thus causes ineffective erythropoiesis.[129,130] Because adult hemoglobin consists of a tetramer of two α and two β chains, inherited mutations at the β globin locus cause a mismatch in the ratio of these two chains, thus preventing the correct assembly of the hemoglobin molecule. Clinically, this may result in transfusion-dependent anemia, which in turn can promote the serious side effect of iron overload. In general, disease severity correlates with the degree to which inactivation mutations inhibit β-globin expression. However, other genetic loci can modulate the disease phenotype, for example, by inducing adult expression of the fetal γ-globin gene, which can be efficiently incorporated into functional hemoglobin in place of the β-globin chain.[129,131] In particular, Orkin's group has recently demonstrated that the transcription factor BCL11A plays a major role in switching γ globin off and β-globin expression on during the transition from fetal to adult life.[132] Gene therapy of β-thalassemia is complicated by the requirement for an exact stoichiometry of α- and β-globin chains to facilitate efficient assembly of hemoglobin. Thus, an effective gene therapy vector must be able to facilitate high level expression of β-globin in the range of that mediated by the normal endogenous gene in an erythroid-specific context. Lineage-specific expression of the β-globin chain is particularly important in the context of genetic modification of HSC to prevent high level expression of β globin in nonerythroid hematopoietic lineages.

The lentiviral vector used in the trial mentioned above comprises a SIN configuration with elements from the β-globin LCR driving expression of the β-globin cDNA that has been mutated to enhance β-globin chain stability. Additionally, the vector's expression cassette is flanked by chromatin insulator elements that function to both prevent silencing of the transgene expression cassette by inhibitory chromatin structure surrounding the integration site and to prevent the vector-encoded enhancer from modulating expression of endogenous genes near to the insertion site. An interim report on the findings of the clinical trial describes that in 2007, a single patient with severe transfusion-dependent β-thalassemia major received $CD34^+$ cells transduced with the lentiviral vector described earlier.[51] There was a clear demonstration of clinical efficacy because the patient has been transfusion independent for 15 months. Of note, posttransplant molecular analysis revealed a mild clonal skewing comprising less than 5% of peripheral blood cells. The clone, which harbors a proviral integration within the high-mobility group A2 proteins *(HMGA2)* gene locus, is reported to be stable. Insertion of the provirus into this locus resulted in the production of a 3′ truncated mRNA resulting from the introduction of a cryptic splice acceptor, present in the vector insulator element, into intron 3 of the gene. This truncated mRNA, comprising exons 1 through 3, was expressed at elevated levels because of a loss of negative posttranscriptional regulation by Let-7 miRNAs because the miRNA target sequence in exon 5 was lost. *HMGA2* has been found to be mutated in chromosomal translocations primarily in benign tumors and less often in malignant tumors.[133] Although the clinical implications of this clonal outgrowth are unclear, this event clearly demonstrates that lentiviral vectors can contribute to insertional mutagenesis albeit in this case via modulation of posttranscriptional regulation of gene expression. Indeed, the propensity to insert in coding sequences may lead to an abundance of abnormal mRNA splicing variants.

Several additional trials are planned using a similar approach to express either a sickle-resistant mutated β-globin protein (as earlier), γ–globin, or based on recent data showing "cure" of humanized sickle mice by genetic deletion of BCL11A expressing shRNA against this transcription factor.[134] These trials represent important extensions of the technology from very rare diseases to a disease with a much larger patient population.

INSERTIONAL MUTAGENESIS

From an early stage in the development of retroviral vectors for gene therapy applications, there has been a concern that recombinant vectors could elicit cellular transformation by altering expression of either cellular proto-oncogenes or tumor suppressor genes that are proximal to the genomic integration site. This phenomenon, referred to as insertional mutagenesis, was characterized as a property of wild-type γ-retroviruses. Having greatly reduced the likelihood that retroviral gene therapy vectors could generate replication competent virus, the risk of a recombinant vector being able to transform a cell via insertional mutagenesis was initially perceived by many investigators to be very low.[135] The lack of efficacy in preclinical models using human hematopoietic stem and progenitor ($CD34^+$) cells also shifted emphasis away from the risks of insertional mutagenesis. However, soon after the publication detailing the efficacy of the Paris-based SCID-X1 trial, work emerged from the group of Baum and colleagues[4] that would reestablish the importance of insertional mutagenesis as a significant risk factor in the retroviral-mediated genetic correction of hematopoietic cells and that ultimately predicted the appearance of leukemia in the SCID and WAS gene therapy trials (X-Linked Combined Immunodeficiency, earlier). Baum demonstrated for the first time that a replication incompetent retroviral vector backbone designed for gene therapy applications could cause cellular transformation via insertional mutagenesis in the context of a transplant model of transduced murine HSCs.[84] In this and a subsequent study, it was found that a single retroviral insertion in the vicinity of the ecotropic viral integration site 1 *(EVI1)* gene or the related PR domain containing 16 *(PRDM16)* gene resulted in their overexpression likely because of the influence of the LTR viral enhancer element and was sufficient to initiate a cascade of events resulting in leukemic transformation in vivo.[84,136] Furthermore, a high copy number infection of murine BM with recombinant retroviral vectors was able to facilitate combinatorial hits which caused leukemogenesis.[85] The pattern of cellular genes that combine to promote cellular transformation demonstrated a significant overlap with those that are deregulated in experiments that used replication competent retrovirus vectors to provoke the development of leukemia.[85] Although murine HSCs likely represent a more readily transformed target than their human counterparts, these studies formally established the mutagenic potential of recombinant retroviral vectors intended for gene therapy applications.

Baum's group then made the seminal observation that at low copy number, retroviral-transduced murine HSCs are selectively expanded during transplant dependent upon proviral insertion sites.[86] These nonmalignant dominant clones are enriched for proviral integration sites in the locale of genes encoding signal transduction molecules and growth promoting genes.[86,137] Analysis of mRNA expression levels in these clones revealed that the proviral insertion did indeed alter transcriptional regulation of genes proximal to the integration site and led to the hypothesis that this was a powerful method to identify pro-engraftment genes through positive selection. These observations were found to have direct translational relevance in the gene therapy trial for CGD where the nonmalignant expansion of dominant retroviral transduced clones in two patients was found to correlate with insertional upregulation of growth promoting genes.[107] Subsequent experience with γ-retroviruses used in the clinical trial for WAS confirmed that insertional leukemogenesis in the SCID-X1 trial was not a disease-specific side effect. At least three children in the WAS trial have developed T-cell leukemia.[124a] Thus far, leukemias associated with replication-incompetent retrovirus vectors are associated with insertional activation of known proto-oncogenes by viral promoter and enhancer sequences (reviewed by Kohn et al[138]).

Wild-type and recombinant retroviral vectors (including α, γ, spuma, and lenti) integrate into the host genome in a semirandom

manner and demonstrate insertion site biases that are dependent on the accessibility of the insertion site in the target cell and variations in the viral integrase enzyme that depend on retroviral genus.[57,139,140] Gammaretroviruses such as MLV have been shown to exert a clear preference for integration in the region immediately surrounding the TSS of actively transcribed genes.[57,87,141,142] Although lentiviral vectors also demonstrate a preference to integrate within the loci of actively transcribed genes, their integration profile favors sites that are downstream of the TSS within the body of the primary transcript.[57,87,88,143-146]

Using viral chimeras, it has been shown that incorporation of MLV integrase into an HIV-1–based vector alters the integration pattern of the lentivirus to more closely resemble that associated with a gammaretroviral vector.[147] It is possible that this phenomenon results from the binding of the MLV integrase with cell type–specific transcription factors resulting in the recruitment of the preintegration complex to the promoter and enhancer region of actively transcribed genes.[148] This work clearly demonstrates that gammaretroviral and lentiviral vectors have developed distinct mechanisms of integrase-dependent integration that may have an impact on the mutagenic potential of recombinant retroviral vectors. If one considers the possibility of integrating vectors upregulating oncogene expression via either readthrough transcription or enhancer effects on the endogenous promoter, then gammaretroviral vectors could be considered as potentially more mutagenic than lentiviral vectors in this context because of their preference for integration near the TSS. Conversely, preferential integration within the body of the primary transcript may result in lentiviral vectors having a higher probability of interrupting, for example, tumor suppressor gene expression or as noted earlier in the treatment of one patient with thalassemia in altering normal gene splicing. Progress has been made in the development of model systems to functionally evaluate the relative mutagenic potential of different vector systems. However, the model systems developed to date have a clear preference to detect mutagenesis mediated via upregulation of oncogene transcription. It is not clear whether this is a reflection of tumor suppressor gene inactivation being inconsequential as a mechanism of insertional mutagenesis or is a result of bias within the model system. Clearly, the preliminary results from the β-thalassemia trial described earlier demonstrate that lentiviral vectors may mediate insertional mutagenesis via alternate mechanisms.

As noted earlier, other related retroviral vector systems have also been shown to have an integration pattern that is distinct from gammaretroviral vectors and as such may represent a safer vector configuration. Recombinant foamy virus vectors do not preferentially integrate within genes, and their integration pattern does not significantly correlate with actively transcribed genes.[149] Likewise, avian sarcoma leukosis virus vectors do not favor gene-rich regions or TSS as preferred integration sites.[59] However, these novel vectors systems have not been as well characterized as gammaretroviral or lentiviral vectors with regards to safety and efficacy and have not yet been translated to clinical use in the near future.

RECENT MODIFICATIONS OF VECTOR SYSTEMS BASED ON CLINICAL EXPERIENCE

New Cell Targets in Genetic Engineering

Despite recent advances in improving ex vivo manipulation of HSC for the purpose of gene transfer, an ongoing limitation of this technology is the loss of engraftment potential of manipulated cells. This is dramatically emphasized in genetic diseases such as Fanconi anemia, in which the disease process itself leads to a marked reduction in HSC targets and in addition HSCs, which appear to have increased susceptibility to in vitro stress.[150,151] An exciting area of recent research advances that may in the future address this issue and also allow prescreening at the molecular level of insertions to determine safety is the use of embryonic stem (ES) cells. These cells offer exciting possibilities for studying mechanisms of pluripotency; establishing models for disease-specific investigations; and enabling future applications in genetic and cellular therapies, including tissue engineering for regenerative medicine. ES cells can be propagated and expanded in vitro, making them amenable to manipulations, including the genetic correction of molecular defects. ES cells can be differentiated into a number of cells resembling mature cell types in vitro.[152] In theory, cell therapy using donor cells of the same genetic constitution as the recipient may avoid the issues related to the immune barrier of allogeneic transplantation. One of the key ethical and practical barriers to applying ES cell research to human diseases is the need for obtaining human oocytes or embryos for the in vitro generation of ES cell lines.

A key recent finding with potential applications to cell and gene therapy has been the observation that many somatic tissues can be "reprogrammed" into pluripotent stem cells with characteristics of ES cells. These cells have been termed *induced pluripotent stem* (iPS) cells, and direct reprogramming of differentiated somatic cells by gene transfer of a small number of defined transcription factors has been shown to yield cells that are indistinguishable from inner cell mass-derived ES cells. Takahashi et al reasoned that forcing the expression of ES cell–specific genes, particularly transcription factors in somatic cells might induce (reprogram) somatic cells to take on the properties of ES cells, much like factors present in oocytes can reprogram somatic nuclei in mammals.[154] By systematic screening experiments, four factors, including some known to be involved in the process of self-renewal (Oct3/4, Sox2), and others associated with transformation and maintenance of ES cell pluripotency (c-Myc, Klf 4), were identified as sufficient to achieve reprogramming. The resultant cells, termed iPS cells, exhibited key features of ES cells, including the fulfillment of stringent pluripotency requirements.[154-156] This work was subsequently confirmed and expanded upon by other groups describing the application of this technology to human cells.[157-160] Proof-of-concept for the utility of iPS cells in regenerative medicine of inherited blood disorders was recently provided when iPS cells were generated from tail tip fibroblast in a humanized sickle cell anemia mouse model. The genetic sickle hemoglobin defect of the iPS cells was corrected in vitro via homologous recombination. Using established protocols for the differentiation of hematopoietic progenitors from ES cells,[161,162] hematopoietic cells capable of reconstituting lethally irradiated recipient mice were generated.

Transplantation of these cells into irradiated recipients resulted in robust engraftment and amelioration of the sickle cell phenotype in transplant recipients.[163] Reprogramming of a panel of disease-specific human iPS cells, including patients with blood diseases, has been demonstrated.[164] Human iPS cell lines shared defining features with human ES cells, including morphology, proliferation, feeder dependence, surface markers, gene expression, promoter and telomerase activities, in vivo differentiation, and teratoma formation. In analogy to the murine system, the reprogramming viruses are strongly silenced in human iPS cells, indicating that the maintenance of pluripotency does not depend on continuous transgene expression.[157-159] Enforced transgene expression appears to initiate a sequence of stochastic events over several days that eventually induces a small fraction of cells (0.001%-0.5% of cells) to acquire a stable pluripotent state. During direct reprogramming, gradual changes lead to a stable epigenetic state that is indistinguishable from inner cell mass-derived ES cells. For example, the Dnmt3a and Dnmt3b methyltransferases become activated and silence the viral transgenes as endogenous pluripotency factors are transcriptionally reactivated.[165,166] Human iPS cell lines thus represent a novel stem cell population that can be studied with regard to normal and pathologic tissue formation in vitro, enabling disease investigation, drug development, and a platform for producing autologous cell therapies that avoid immune rejection. Moreover, the creation of iPS cells allows the correction of genetic defects and exhaustive molecular characterization at the clonal level before tissue reconstruction. Unfortunately, the genetic transduction with exogenous genes, particularly oncogenes such as *c-MYC* and *KLF4,* and the use of integrating retroviral delivery systems are clear handicaps of this technology with regard to future clinical translation. In addition, to date robust reconstitution of murine hematopoiesis has not been consistently demonstrated and there no successful reports of

in vivo reconstitution of human hematopoiesis in model systems. These all represent significant barriers to the translation of this powerful technology into human therapies.

One utility of targeting iPS cells for genetic therapies is that these cells can be cloned and expanded, allowing analysis of vector insertion sites before clinical use. In addition, reprogramming has now been accomplished, albeit at lower efficiencies using both nonintegrating vectors and protein transduction.[167-170] Reprogramming has also now been accomplished with the expression of fewer transcription factors,[170,171] most notably without c-Myc. Several laboratories have demonstrated that targeting specific loci is associated with limited or no adverse effects on expression of neighboring genes (reviewed by Sadelain et al[172]). Most notably, targeting of the *AAVS1* locus located on chromosome 19 has been well characterized.[173,174] This locus encodes the *PPP1R1C* gene that is ubiquitously expressed. Insertion at this site appears to provide a "safe harbor" with respect to genotoxicity and allows stable and long-term expression of transgenes in human embryonic stem cells (hHSCs).[173] Finally, Naldini and colleagues[175] have recently demonstrated that targeted insertion into two genomic sites (*IL2RG* and *CCR5*) using zinc-finger technology leads to no detectable alteration in the expression of nearby genes and sustained expression of the transgene cargo. The frequency of directed site-specific integration in primary fibroblasts was as high as 10%.[175] In addition, elegant work by Sadelain and colleagues[176] has demonstrated the feasibility of screening large numbers of iPS-derived clones for both integration in operationally defined safe harbors and for clinically relevant transgene expression using vectors that express globin genes.[176] Thus, this approach offers exciting future applications in treating a variety of human diseases.

Site-Directed Homologous Recombination to Correct Gene Mutations

A long-standing but unrealized goal of genetic therapy has been homologous recombination to affect *replacement* of abnormal disease-causing gene mutations. Although human ES cells theoretically provide an ideal target for such correction,[177-183] gene targeting in these cells has proven difficult. Zinc-finger nuclease (ZFN = mediated DS breaks allow high-efficiency site-specific homologous recombination and has been used to target a number of genes in human cells.[184,185] ZFNs are generated by fusing the FokI nuclease domain to a DNA recognition domain composed of engineered C2H2 zinc finger motifs that specify genomic DNA binding site for the chimeric protein. Compared with standard homologous recombination vectors, one advantage of ZFN is the relatively short stretch of homology needed (500 bp vs. 10-12 kb) to mediate genomic targeting. Binding of two fusion proteins to cognate DNA allows dimerization of the nuclease, leading to generation of a DS DNA break. When donor DNA with homology to sequence flanking the DS break is present, repair occurs with incorporation of the incoming DNA sequence. This system has been successfully used to target genes in multiple species and has recently been demonstrated in both human ES cells and iPS cells to effectively target both expressed and nonexpressed genes with a frequency of 1% to 20%[173,175,186,187] and has been termed *genome editing*. Because the development of a DNA DS break is a prerequisite to ZFN-mediated gene editing and such breaks induce both p53 and HDR, this approach, although attractive, could also have significant "off-target" effects. In addition, if efficiency improves, direct targeting in HSC could also be envisioned.

Other systems that seek to target specific genetic loci have also been described and are at different levels of development. As with ZFN nucleases, these approaches use cellular DNA repair mechanisms to introduce exogenous DNA sequences into the chromosome. Thus, methods to increase the efficiency of targeting by introducing DNA DS breaks, and several methods have exploited endonucleases that target rare DNA sequences to establish these DS breaks. Alternative methods in development include meganucleases[188] and transcription activator–like effector nucleases.[189] Challenges of all of these approaches include efficiency of targeting in primary cells and potential off-target effects on the genome and will likely also depend on technologic advances that allow ex vivo HSC cloning and large-scale expansion. At present, the use of ES or iPS cells is clearly amendable to this approach, but as noted earlier, use of these cells to derive transplantable HSC is a major impediment to clinical utilization.

FUTURE DIRECTIONS

The use of gene transfer to treat human diseases has now been successful in several diseases. Compared with allogeneic BMT, ex vivo gene therapy using autologous cells eliminates the risk of GVHD and in some cases reduces the intensity of preparative regimen required before transplant, which also reduces toxicity. Thus, in some diseases, this therapeutic approach can now be considered an alternative to standard therapy. Insertional mutagenesis, which has resulted in serious adverse events in several trials, has stimulated rapid development of putative safer vector systems that are being tested in human trials but remains a challenge. Rapid progress in molecular technology, such as high-throughput sequencing and the development of new sources of expandable stem cell sources, offers significant potential for ongoing development of gene transfer in regenerative biology for a wide range of human conditions.

ACKNOWLEDGEMENTS

Funding from NIH DK062757, CA113969, AI097628, DK090913, and the NHLBI Gene Therapy Resource Program. I would like to thank members of my laboratory and particularly Michael Milsom and Lars Mueller for helpful discussions and members of the Transatlantic Gene Therapy Consortium for productive collaborations.

CHAPTER 100

MESENCHYMAL STROMAL CELLS

Edwin M. Horwitz

Mesenchymal stromal cells (MSCs) are spindle-shaped plastic adherent cells isolated from bone marrow and from many other tissue sources. Although MSCs were first described in the study of bone marrow, little interest in these cells occurred over the subsequent two decades. The remarkable resurgence of interest among hematologists and, in particular, specialists who perform hematopoietic cell transplantation (HCT) represents a full circle in the study of MSC biology and therapy.

It was Alexander Friedenstein, during his pioneering work studying the bone marrow as the organ of hematopoiesis, who first identified the cells that now bear the designation *MSC*.[1] He showed that these cells contributed to the hematopoietic microenvironment and could support hematopoiesis in vitro[2] as well as serving as precursors for osteoblasts.[1] Noting that a small subset of cells demonstrated a high proliferative potential by forming clonal colonies when plated at low density (termed *CFU-F* by Friedenstein in analogy to hematopoietic colony-forming units), Owen proposed the concept of a stromal stem cell that could repopulate the marrow microenvironment as the hematopoietic stem cell can repopulate hematopoiesis.[3-5]

The term *mesenchymal stem cell* was proposed by Arnold Caplan, who hypothesized that this cell could differentiate to a wide variety of mesenchymal tissues and proposed a broad lineage "tree," suggesting that the mesenchymal stem cell could give rise to bone, cartilage, muscle, hematopoietic-supportive stroma, tendon, ligament, adipose, and other connective tissues.[6] This notion attracted the attention of investigators in the emerging arena of regenerative medicine. Despite efforts to exploit MSC-based therapy in hematology, definitive indications of potential clinical benefits have not been obtained; hence the focus of MSC research has shifted to regenerative medicine.[7,8]

Most recently, investigators have recognized the ever-increasing spectrum of cytokines secreted by ex vivo–expanded MSCs, the striking immunomodulatory properties of the cells, and the fact that the mechanism of therapeutic activity in virtually all cases has been through paracrine effects—the release of soluble mediators. Collectively, these observations have spurred a renaissance of MSCs in hematology.

NOMENCLATURE AND THE DEFINING PHENOTYPE

The nomenclature of these cells merits clarification. MSCs have been designed by a wide variety of terms including *marrow stromal cells, marrow stromal fibroblasts,* and most frequently, *mesenchymal stem cells,* which was the basis for the abbreviation *MSC*. The various monikers have created some confusion in the literature, as some would suggest that they refer to different cell types. Although the specific properties of MSCs isolated in the laboratory may vary depending on the methods employed, the assortment of terms, in general, refers to the same heterogeneous population of cells.

The notion that all MSCs that have been isolated and expanded in the laboratory are stem cells remains unproven. *Stem cells* are defined as having the capacity for extensive self-renewal and differentiation to two or more distinct lineages in a physiologically relevant manner. Thus studies are needed to demonstrate that a given cell can undergo self-renewal and give rise to terminally differentiated lineages in situ. Although important studies are emerging, comprehensive unifying data to define a clinically relevant mesenchymal stem cell are yet to be reported.

This idea is not intended to dispel the notion that a mesenchymal stem cell may exist, or at least a stem cell for the bone marrow microenvironment as proposed by Owen. Indeed, emerging data suggest that a rare cell within the population of adherent cells that we designate MSCs or some other, adherent or nonadherent, cell population may be a mesenchymal stem cell. Nonetheless, the unfractionated population of MSCs isolated by plastic adherence does not seem to meet the criteria of a homogeneous population of stem cells. Therefore in 2005, the Mesenchymal and Tissue Stem Cell Committee of the International Society for Cellular Therapy (ISCT) recommended that the term *mesenchymal stromal cell* is a more appropriate designation for this heterogeneous population of cells, maintaining the abbreviation *MSC* for that term and reserving the term *mesenchymal stem cell* for a subset of these (or other) cells that demonstrate stem cell activity in vivo by clearly stated criteria.[9]

Although MSCs have not been proven to be stem cells, they do seem to possess significant clinical potential. Accordingly, a system to easily identify the cells is imperative. Unfortunately, no single clinically validated cell surface marker (analogous to CD34 expression on human hematopoietic stem cells) has been universally accepted, nor is there a single functional assay (analogous to hematopoietic repopulating assays) to define MSCs.

To begin to address this issue, the Mesenchymal and Tissue Stem Cell Committee of the ISCT sought in 2006 to standardize a working definition of MSCs by proposing a set of minimal criteria to denote these cells.[10] First, MSCs must be plastic-adherent when maintained in standard culture conditions. Second, MSCs must express CD105, CD73, and CD90, and they must lack expression of CD45, CD34, CD14 or CD11b, CD79 or CD19, and HLA-DR surface molecules. Third, MSCs must differentiate to osteoblasts, adipocytes, and chondrocytes in vitro (Fig. 100-1). Although novel surface markers expressed by MSCs have been described,[11,12] these criteria remain the most applicable. As new knowledge unfolds, however, these guidelines will likely require modifications; as modifications continue, it is hoped that a simpler system will emerge.

IDENTIFICATION AND PHYSIOLOGIC ROLE OF MESENCHYMAL STEM CELLS

The physiologic cell that corresponds to the isolated and expanded cells is of great interest to investigators of bone marrow biology and may reveal novel therapeutic applications. However, only recently has evidence as to the origins of MSCs begun to emerge.

Sacchetti and colleagues identified a CD146-expressing stromal cell from human bone marrow.[13] In situ, these CD146 cells reside in the subendothelial layer in sinusoidal walls as adventitial reticular cells. CD146 expression is found on all CFU-Fs and their clonal progeny, but on only about 30% of the heterogeneous populations of stromal cells. After isolation and ex vivo expansion, the CD146-expressing cells were capable of forming the hematopoietic microenvironment, including bone and marrow space, in heterotopic locations

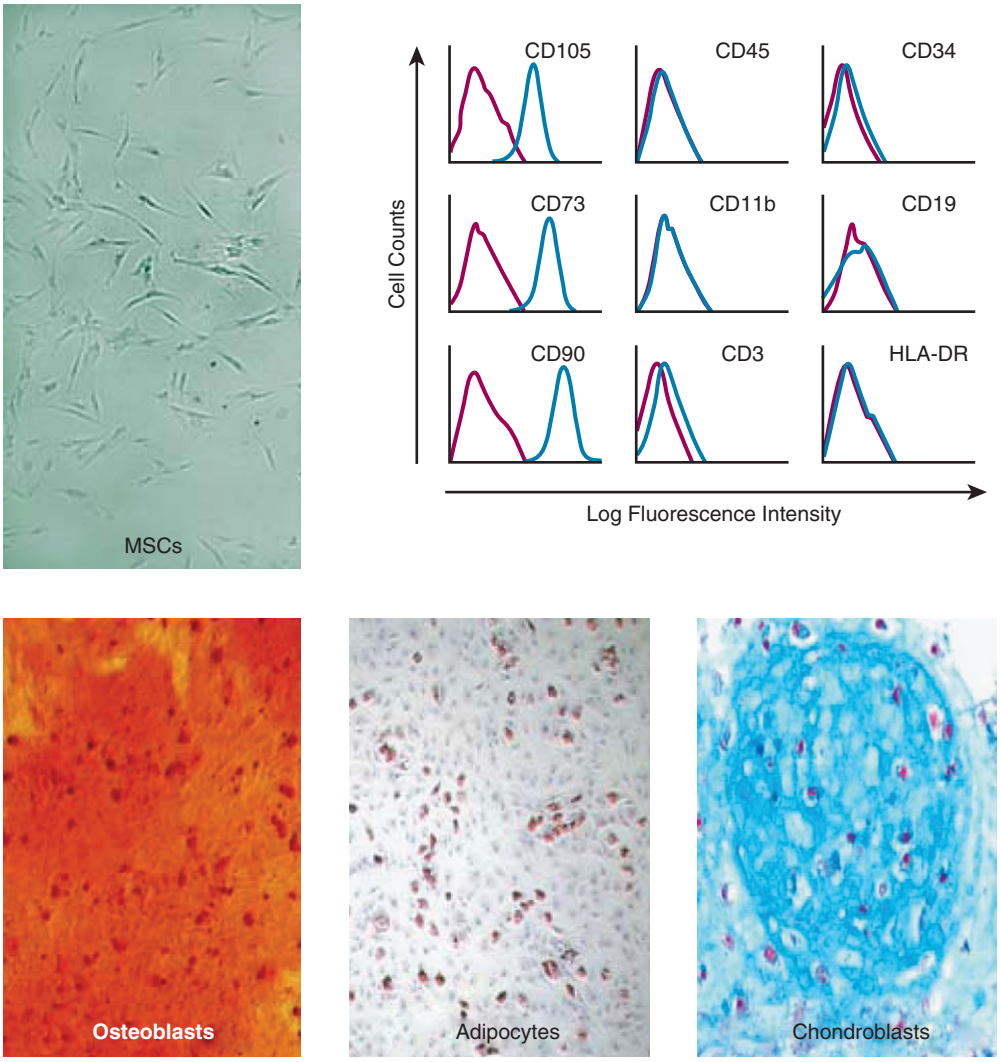

Figure 100-1 A PANEL OF DATA DEMONSTRATING THE DEFINING CHARACTERISTICS OF MSCS: ADHERENCE, IMMUNOPHENOTYPE, AND IN VITRO DIFFERENTIATION. *Top left,* Photomicrograph of undifferentiated MSCs showing the characteristic spindle shape and adherent properties of the cells. Original magnification, × 40. *Top right,* Flow cytometry histograms demonstrating the typical expression pattern of surface antigens (—) and isotype control (—), as indicated. *Bottom,* Immunocytochemical staining demonstrating the differentiation of MSCs into osteoblasts (Alizarin Red stain), adipocytes (Oil Red O stain), and chondroblasts (Alcian Blue stain). *(With permission from Martinez C, Hofmann TJ, Marino R, et al: Human bone marrow mesenchymal stromal cells express the neural ganglioside GD2: A novel surface marker for the identification of MSCs.* Blood *109:4245, 2007.)*

after subcutaneous transplantation into immune deficient mice. Bone was evident at 4 weeks after transplantation. Then capillaries formed and developed into a system of sinusoids similar to human bone marrow. The endothelium of the sinusoids was murine, but the adventitial cells were human, indicating that the transplanted human adventitial cells were capable of self-renewal. Adipocytes were also observed in the developing marrow space. By 8 weeks, murine hematopoietic cells had migrated into and colonized the marrow space of the regenerated bone. Thus the CD146-expressing cells isolated from human bone marrow and accounting for all CFU-Fs seemed to be able to give rise to bone, and the entire bone marrow microenvironment was sufficient to attract primitive hematopoietic cells and support the ensuing hematopoiesis.

Crisan and colleagues reported that CD146-expressing cells exist as pericytes in multiple human organs.[14] These cells expressed typical MSC markers, lacked hematopoietic markers, and differentiated to osteoblasts, adipocytes, and chondrocytes, thereby meeting the criteria for MSCs. Of interest, the cells exhibited myogenic potential in vitro and in vivo. These studies bear resemblance to prior reports suggesting that MSCs isolated from different tissue sources show different gene expression profiles and the expression patterns, in some cases, seem to reflect the tissue from which they were derived.[15] Moreover, these two studies are consistent with the evolving paradigm of MSCs that ostensibly similar cells isolated from different tissues may have markedly different biologic—and therapeutic—potential. Furthermore, it underscores the need to consider the source of MSCs in the development of MSC-based cell therapies.

Although murine MSCs share some characteristics with their human counterparts, they also seem to differ in many ways[16]; hence murine studies of MSC biology must be interpreted with the understanding of potential interspecies differences. Such caution notwithstanding, murine studies have also shed light on the physiologic role of MSCs. Morikawa and colleagues identified a subset of cells from the heterogeneous population of MSCs of murine bone marrow characterized by platelet-derived growth factor receptor α (PDGFRα) and stem cell antigen 1 (Sca 1), termed *PαS cells*.[17] The population was highly enriched for CFU-Fs, expressed common MSC markers, was capable of self-renewal in vitro, and underwent differentiation to osteoblasts, adipocytes, and chondrocytes. Unexpectedly, these cells also seemed to differentiate to endothelial cells. In healthy mice, the

cells were found in the perivascular space, similar to the human CD146-expressing cells, which we presume are human MSCs.[13,14] After intravenous transplantation of freshly isolated cells (without ex vivo expansion), the PαS cells gave rise to osteoblasts and adipocytes, as well as perivascular cells, consistent with stem cell–like behavior.

Finally, Mendez-Ferrer and colleagues[18] have identified a nestin-expressing MSC within murine bone marrow. Although the cells were found exclusively in the perivascular region adjacent to bone or within the bone marrow, they were distinct from typical vascular endothelial cells. The nestin-expressing MSCs contained all CFU-Fs and exhibited the differentiation characteristics attributed to MSCs. Of note, the cells were able to undergo self-renewal in serial transplantation, although they were propagated in vitro as nonadherent aggregates termed *mesenspheres*. In vivo, these cells were intimately associated with hematopoietic stem cells and seemed to be critically important for hematopoietic stem cell homeostasis and marrow homing of transplanted hematopoietic stem cells.

These studies illustrate the important, evolving paradigm of mesenchymal stem cells; however, MSCs as agents of cell therapy, after isolation and ex vivo expansion, may bear little biologic resemblance to their physiologic counterparts in situ. Thus the engineered biology of ex vivo–expanded MSCs is critically important to the development of effective cell therapy.

Cell biology of Ex Vivo–Expanded Mesenchymal Stromal Cells for Clinical Cell Therapy

Source

MSCs for clinical applications are most commonly isolated from bone marrow[19] but have also been obtained from adipose tissue,[20,21] umbilical cord blood,[22,23] and placenta.[24] Other reported sources include amniotic fluid[25] and fetal tissues such as lung, liver, and blood.[26] Mobilized peripheral blood cells have been reported as a source of MSCs[27]; however, current consensus is that MSCs do not appreciably circulate in cytokine mobilized or steady-state peripheral blood. Reports of MSCs in umbilical cord blood have also been conflicting; however, recognizing that cord blood unit storage time, volume, and cell count are critical parameters affecting the efficiency of MSC isolation,[23] general agreement now exists that MSCs do reside within cord blood.

Isolation

MSCs are most often isolated by "adherence selection." For bone marrow, mononuclear cells are placed in tissue culture, and the MSCs will adhere to the plastic surface of the tissue culture vessel. The identification of new surface markers has led to the prospective isolation of MSCs using immunomagnetic beads or FACS sorting of freshly prepared mononuclear cell preparations. GD2, CD271, and frizzled-9 have been shown to serve as effective markers for the isolation of MSCs[11,12,28,29]; however, in all cases, culture expansion of the selected cells was required to obtain a sufficient sample for further study. If prospective isolation of MSCs is to become a common practice, a substantial advantage must be demonstrated.

Expansion

MSCs have a remarkable capacity for ex vivo expansion. In standard culture conditions, MSCs isolated by adherence selection demonstrate a population doubling time of about 2 to 5 days[30]; however, plating cell density can impact the expansion potential.[31] Most MSC preparations can be maintained in continuous culture for 4 to 6 months before senescence. MSCs isolated from different species exhibit differing growth potentials. Although human MSCs rapidly expand in culture, murine MSCs expand more slowly. Moreover, different mouse strains show a marked difference in growth and differentiation.[16]

All MSC cultures, at present, require some serum supplementation. Fetal bovine serum is the most commonly used supplement, but the translation of MSCs to the clinics and the report of a clinically significant immune response against fetal bovine serum proteins in one patient who received MSCs[32] has led to the development of human serum supplementation strategies. Human serum containing a platelet lysate[33] is rapidly becoming the principal supplement; however, supplementation with recombinant growth factors with or without human serum is also developing.

Phenotype

The expanded MSC product is a heterogeneous population of cells most easily demonstrated by in vitro adipocyte differentiation, in which only a subset of cells develops cytoplasmic fat globules, and a CFU-F assay, in which a small fraction of cells exhibit a high proliferative, colony-forming potential. However, this assorted population does have some common characteristics. The uniform surface phenotype of MSCs includes expression of CD105, CD73, and CD90, which can be used to define the cells, as well as CD49b, CD49e, and CD166. STRO-1, an IgM monoclonal antibody generated by inoculating mice with human $CD34^+$ cells, binds to human MSCs (or perhaps MSC precursors) in freshly isolated bone marrow but does not bind to murine MSCs or human MSCs in tissue culture.[34] The antigen recognized by STRO-1 has not been identified. The low-affinity nerve growth factor receptor, LNGFR or CD271, is also expressed on human MSCs in freshly harvested bone marrow but not in culture-expanded cells.[28] Ex vivo–expanded MSCs lack expression of hematopoietic and endothelial antigens, CD34, CD45, CD3, CD19, CD14, CD11b, and CD31.

MSCs demonstrate a surface antigen profile predicted to be hypoimmunogenic. At baseline, MSCs express moderate levels of HLA class I molecules but lack expression of HLA class II molecules on the cell surface. Upon stimulation with interferon γ in vitro, class II antigens are found on the cell surface.[35] MSCs do not express the costimulatory molecules CD80, CD86, CD40, and CD40L.[35,36]

One of the most distinguishing characteristics of MSCs, in contrast to other spindle-shaped, plastic-adherent cells, is the capacity for trilineage differentiation in vitro. MSCs differentiate to osteoblasts, chondrocytes, or adipoctyes when cultured under lineage-specific inductive conditions, and the cells can be identified by either tissue-specific immunohistochemical staining (e.g., Oil Red O to identify the cytoplasmic fat globules of adipocytes) or by gene expression.

Secretome

MSCs have an enormous capacity for secretion of soluble mediators, and indeed, it is these mediators that constitute the principal mechanism of biologic/therapeutic activity. MSCs secrete stromal cell–derived factor-1 (SDF-1),[37] which plays a critical role in the homing of hematopoietic stem cells to the marrow niche.[38] In vitro, MSCs constitutively secrete interleukin 6 (IL-6), IL-7, IL-8, IL-11, IL-12, IL-14, IL-15, macrophage colony-stimulating factor (M-CSF), Flt-3 ligand, and stem cell factor (SCF). Upon IL-1α stimulation, MSCs are induced to further express IL-1α, leukemia inhibitory factor (LIF), granulocyte colony-stimulating factor (G-CSF), and granulocyte-macrophage colony-stimulating factor (GM-CSF).[35,39] Finally, MSCs can secrete several chemokine ligands, including CCL2, CCL4, CCL5, CCL20, CX_3CL1, and CXCL8.[40]

It is important to note that the list of cytokines secreted by MSCs is rapidly growing. The secretome of an MSC product is, in part, dependent on the tissue source and the conditions of ex vivo expansion.[15,41] In theory, then, specific tissue sources can be identified, and specific expansion protocols can be developed to generate a secretome that is especially well suited for specific clinical indications. Indeed,

exceptionally active investigation continues in the search for as-yet-undescribed cytokines generated by MSCs and processing conditions to induce expression of specific cytokines or other mediators.

Homing and Migration

Ex vivo–expanded, intravenously infused MSCs have been reported to preferentially migrate to sites of tissue damage, and this property can potentially be exploited in regenerative medicine to enhance tissue repair.[42,43] Additionally, these cells seem to migrate to solid tumors and incorporate into the tumor stroma.[44] Whether MSCs inhibit or promote tumor growth is a matter of ongoing debate. Homing does not seem to be important for potential therapeutic activity of MSCs for hematologic applications.

Life Span of Mesenchymal Stromal Cells

The turnover rate of bone marrow MSCs in situ is unknown. More relevant to clinical applications of MSCs is the life span of ex vivo–expanded MSCs after intravenous infusion. Although a definitive answer may be difficult to conclusively prove, three lines of evidence suggest MSCs persist about 6 to 9 months in the recipient. First, Nolta and colleagues infused human IL-3–secreting MSCs into NOD-SCID mice to support human hematopoiesis and were able to detect human IL-3 in the murine serum for up to 9 months.[45] Second, Horwitz and colleagues infused human MSCs into children with osteogenesis imperfecta and observed a striking acceleration of growth velocity over the first 6 months with a far slower rate of growth over the subsequent 6 months.[32] After 1 year, the growth rate approximated the rate before the MSC infusion. Finally, Keating infused autologous MSCs gene-marked with the factor IX cDNA into three adult patients after autologous HSCT for a hematologic malignancy. Gene-marked cells were identified in recipient culture–expanded MSCs obtained from bone marrow aspirations up to 8 months after the MSC infusion. Studies at 12 months were consistently negative.[46]

Immunobiology of Ex Vivo–Expanded Mesenchymal Stromal Cells

Although the specific interactions of MSCs with the immune system and the mechanisms of those interactions remain to be fully elucidated, MSCs clearly have a profound impact on immunity.[47] The field of MSC-mediated immune modulation continues to evolve, but several overriding themes have emerged. First, MSCs interact with all arms of the immune system (Fig. 100-2). Second, there seems to be a dynamic cross-talk between the immune effector cells and MSCs, suggesting that MSCs may play a physiologic role in regulating the immune response. Third, unfortunately, the data are often conflicting, with many reports diametrically opposed to the research of others, indicating the need for additional studies to fully understand the MSC-immune system interaction. The immunomodulatory properties of MSCs may be exploited therapeutically in hematopoietic cell transplantation to suppress graft rejection, treat severe graft-versus-host disease (GVHD), and possibly prevent clinical GVHD. Indeed, the recognition that MSCs can suppress the immune response is what attracted the collective attention of the HCT community.

T Lymphocytes

The first studies to suggest that MSCs may possess inherent immunomodulatory properties were based on the recognition that ex vivo–expanded third-party human MSCs inhibit the proliferation of allogeneic lymphocytes in a mixed lymphocyte reaction.[48] The effect is nonspecific, because MSCs inhibit the proliferation of T cells in response to alloantigens[36,49-51] and mitogens,[48] and it is MHC-unrestricted, based on the fact that both allogeneic and autologous MSCs generate a similar suppression.[36,49,50,52,53] The antiproliferative effect of MSCs has been reported to resemble divisional arrest anergy of activated T cells based on evidence that MSCs induce a cell cycle arrest in the G_1 phase, which persisted after removal of the MSCs from the in vitro culture.[54] In addition to this antiproliferative effect,

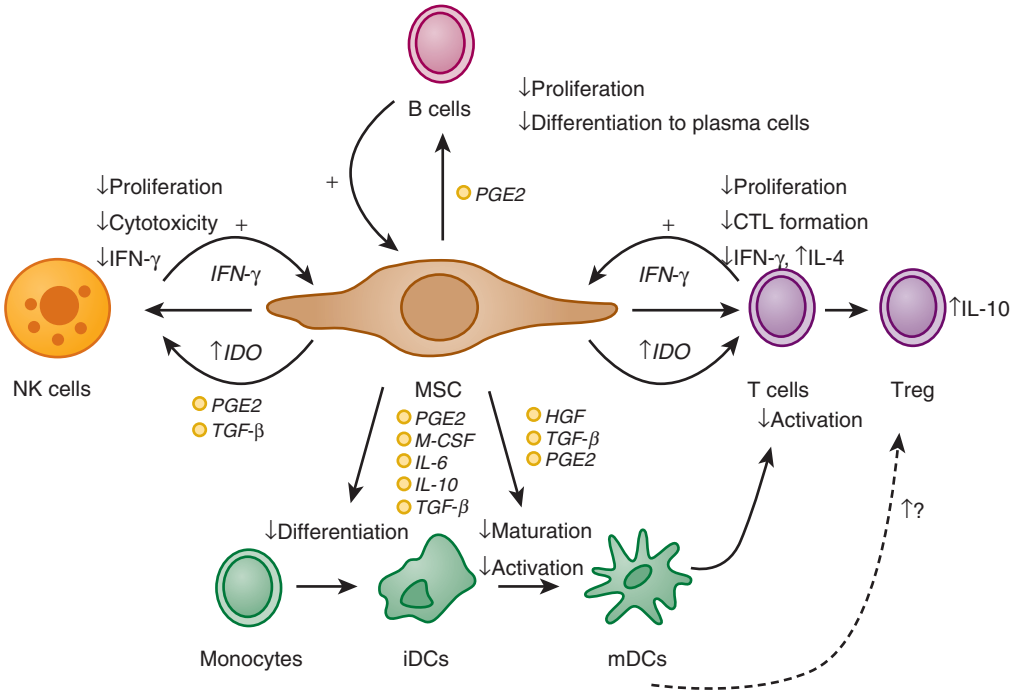

Figure 100-2 A SCHEMATIC REPRESENTATION OF THE PROPOSED IMMUNOMODULATORY EFFECTS OF MESENCHYMAL STROMAL CELLS. *CTL,* Cytotoxic T cell; *HGF,* hepatocyte growth factor; *IDO,* indoleamine 2,3-dioxygenase; *PGE2,* prostaglandin E2; and *TGF-β,* transforming growth factor β. *(With permission from Nauta AJ, Fibbe WE: Immunomodulatory properties of mesenchymal stromal cells,* Blood *110:3499, 2007)*

MSCs may also inhibit the cytotoxicity of T lymphocytes[50] and increase the proportion of $CD4^+CD25^+Foxp3^+$ regulatory T cells, which possess potent immune suppressor activity.[55] Finally, MSCs seem to decrease interferon γ production by Th-1 cells and increase interleukin-4 by Th-2 cells, suggesting a shift from a proinflammatory to an antiinflammatory state.[56]

B Lymphocytes

MSCs also interact with B lymphocytes, although the precise mechanisms are unclear. MSCs seem to inhibit B lymphocyte proliferation in vitro via divisional arrest anergy, impair B lymphocyte maturation and antibody secretion, and decrease the chemotactic properties.[57,58] By contrast, some studies have suggested that MSCs support the survival, proliferation, and differentiation of B lymphocytes to mature, antibody-secreting cells.[59]

NK Cells

MSCs have been reported to inhibit IL-2- and IL-15-induced proliferation of freshly isolated, resting NK cells and prevent the induction of cytotoxic activity and cytokine production; however, proliferation of NK cells preactivated with IL-2 was only partially inhibited.[60,61] Other studies have shown that the cytolytic activity of freshly isolated NK cells is unaffected by MSCs, whereas NK cells cultured with IL-2 and MSCs seem to have reduced, but not absent, cytotoxicity against K562 target cells.[62-64] Of interest, MSCs seem to be highly susceptible to NK cell-mediated lysis due to expression of surface ligands involved in NK cell activation, such as NKG2D and DNAX accessory molecule-1 ligands[60] as well as low-level MHC class I expression.

Dendritic Cells

MSCs can inhibit the differentiation of $CD14^+$ monocytes and $CD34^+$ cells into dendritic cells (DCs), as well as the maturation and function of DCs in vitro.[65-67] MSC coculture inhibited the GM-CSF-, IL-4-induced differentiation of monocytes to DCs, but the inhibition was reversible. MSC-DC coculture also induced mature DCs to downregulate surface expression of CD83, CD1a, CD80, CD86, and HLA-DR, as well as IL-12 secretion. Moreover, MSC-treated DCs showed an impaired capacity to prime allogeneic T cells, consistent with the observation that MSCs direct DCs to acquire a tolerogenic phenotype.

Immune Privilege

MSCs are considered to be immune privileged by many investigators.[68] Indeed, MSCs exhibit a hypoimmunogenic phenotype and do not elicit a T cell–proliferative response in vitro. Moreover, HLA-disparate MSCs can be safely infused into patients and often demonstrate a therapeutic effect, such as in the treatment of GVHD.[69,70] However, it is not strictly correct to infer immune privilege from such data. Immune suppressive activity and immune privilege are distinct biologic properties, and immune suppression does not indicate immune privilege a priori. Murine studies and in vitro studies of human MSCs do not necessarily reflect clinical (in vivo) immune activity, and infusion of allogeneic MSCs into immunosuppressed hosts does not provide data to support (or refute) the immunogenicity of the cells.

Rigorous evaluation of the immune response to allogeneic, HLA-disparate MSCs in immune competent hosts has not yet been reported. However, an early observation suggested that MSCs are recognized by the immune system. Horwitz and colleagues infused gene-marked MSCs into immune-competent children with osteogenesis imperfecta.[32] In this double gene-marking study, MSCs transduced with a nonexpressing retroviral vector were identified in all evaluable patients, whereas MSCs transduced with a vector that expressed neomycin phosphotransferase (neo^R), a bacterial protein, were never found. These data suggest the possibility that the MSCs expressing neo^R were immunologically recognized by the immunocompetent hosts.

The preponderance of current data suggests that MSCs are not intrinsically immune privileged and, in fact, may stimulate an immune response in some conditions. However, MSCs seem to be hypoimmunogenic as a result of their low-level expression of MHC molecules and complete lack of costimulatory molecule expression, and this property may be exploited in a variety of clinical settings. Indeed, the use of allogeneic HLA-unmatched MSCs seems to be safe and does elicit a therapeutic response in some patients.

Risks of Mesenchymal Stromal Cells as Cell Therapy

Malignant Transformation

MSCs invariably undergo ex vivo expansion for all clinical applications. This extensive cell replication raises the possibility of spontaneous transformation to a malignant phenotype, the most serious potential adverse event in a clinical trial. Murine MSCs seem to more readily undergo malignant transformation than do human MSCs,[71] possibly because of their significantly greater susceptibility to chromosomal aberrations and spontaneous mutations with prolonged culture,[72] suggesting such models are not good predictors of transformation of human MSCs in clinical trials.

Although there are several reports of malignant transformation of MSCs in vitro, the two most often cited studies[73,74] have been retracted[75,76] since the authors found their results were due to contamination of the MSC cultures by malignant cell lines. Further studies have confirmed the lack of spontaneous transformation.[77] During ex vivo expansion, MSCs may acquire chromosomal aberrations that have been suggested to predict the likelihood of malignant transformation.[78] However, such theoretical predictions have not been validated, and substantial data to the contrary have been presented.[79,80]

Malignant transformation of MSCs after infusion into human subjects in a clinical trial has never been reported. This may be because it is an exceedingly rare event and there have not yet been sufficient numbers of patients for such an event to occur. Alternatively, the latency for such an event could be quite long. Since MSCs do not seem to survive in the patients for more than 1 year, the likelihood of malignant transformation of ex vivo processed, transplanted MSCs in patients may be significantly less than predicted based on clinical experience with hematopoietic stem cell transplantation,[81] genetically modified hematopoietic stem cells,[82] or karyotype analysis.[80]

It must be emphasized that the field of MSC therapy is relatively young and definitive conclusions are not yet available; however, current opinion favors the notion that malignant transformation is an unlikely outcome and should not impede clinical investigation.

Ectopic Tissue Formation After Systemic Infusion

The potential of MSCs to differentiate to osteoblasts, chondrocytes, and adipocytes in vitro raises the possibility that MSCs may inappropriately differentiate to a mesenchymal tissue, such as bone, after intravenous infusion. Such ectopic tissue formation is thought to be unlikely, because the local environmental cues seem to regulate the differentiation of MSCs. A recent single report of murine MSCs injected into experimentally infracted myocardium demonstrated calcifications at the site of the cell injection.[83] In countless other experimental systems and clinical investigations, however, measurable ectopic tissue formation after systemic infusion of MSCs had never been reported.

Opportunistic Infections

Given the remarkable immune-modulatory capacity of MSCs, there is concern that MSCs may sufficiently suppress patients' immunity,

rendering them susceptible to opportunistic infections. Such an outcome has never been reported, and MSCs seem to exert differential effects on alloantigen and virus-specific T-cell responses,[84] suggesting that MSC therapy is unlikely to induce clinically significant increased risk for opportunistic infections.

Mesenchymal Stromal Cells in Hematopoiesis

The principal application of MSC therapy in hematology is directed toward fostering hematopoietic reconstitution, most commonly (at this time) after hematopoietic cell transplantation. However, early promising results are being reported in regard to MSCs as cell-processing reagents for umbilical cord blood hematopoietic stem/progenitor cell expansion before transplantation.

Hematopoietic Cell Transplantation

MSCs were originally considered to be stem cells composing the hematopoietic supportive element of the marrow space and were studied in an effort to rebuild the microenvironment to foster hematopoietic stem cell (HSC) engraftment after allogeneic transplantation. The marrow microenvironment is, in fact, damaged by the chemoradiotherapy preparatory regimen, which likely disrupts the HSC niche,[18,85] thereby contributing to the delay of hematopoietic reconstitution after both autologous and allogeneic HSCT.[86-88] Although we now recognize that MSCs do not appreciably engraft in the host marrow microenvironment after intravenous infusion, the cells may foster engraftment by immune suppressive mechanisms, which could reduce the risk for graft rejection, or facilitate hematopoietic reconstitution by secreting cytokines into the circulation that would promote hematopoiesis reducing the risk for primary graft failure and hasten the time to neutrophil, erythrocyte, and platelet recovery.

Clinical Studies

The first effort to determine whether MSCs can promote engraftment and hematopoietic reconstitution in patients was reported by Koc and colleagues in 2000.[89] Twenty-eight women undergoing autologous HSCT with mobilized peripheral blood cells for advanced breast cancer were infused with 1 to 2.2×10^6 ex vivo–expanded MSCs/kg 4 hours before the hematopoietic graft. The MSCs were harvested about a month preinfusion, before the patients underwent mobilization for stem cell collection, and expanded for two to six passages. The median time to attain a neutrophil count greater than 500/μL was 8 days (range, 6 to 11 days), and a platelet count greater than 20,000/μL was 8.5 days (range, 4 to 19 days). Definitive clinical conclusions cannot be drawn from this single arm uncontrolled trial, but the rapid hematopoietic recovery demonstrated the potential of MSCs to enhance reconstitution in patients after autologous HSCT.

Lazarus and colleagues assessed the capacity of ex vivo–expanded MSCs obtained from HLA-identical sibling donors to facilitate hematopoietic recovery after cotransplantation with either bone marrow or peripheral blood stem cells in patients with hematologic malignancies.[90] MSCs were isolated, expanded, and cryopreserved before the initiation of the conditioning regimen. The MSC units were thawed at the bedside and intravenously infused into the patients 4 hours before the hematopoietic stem cell graft. The median hematopoietic cell doses were 3.6×10^8 mononuclear cells/kg for bone marrow and 5.0×10^6 $CD34^+$ cells/kg for peripheral blood grafts, whereas the MSC dose ranged from 1 to 5×10^6 cell/kg for both patient groups. Overall, the median time to attain a neutrophil count of 500/μL was 14 days (range, 11 to 26 days) and to attain a platelet count of 20,000/μL, 20 days (range, 15 to 36 days). Patients receiving peripheral blood grafts demonstrated a more rapid neutrophil recovery (median, 13.5 days) compared with those receiving bone marrow (15.5 days). Although this study also lacked a control cohort of patients, the time to neutrophil recovery of bone marrow appears to be slightly faster than usual. On the other hand, it is less clear whether the time to engraftment of PBSC represents a hastening of hematopoietic recovery.

Haploidentical HSCT in children typically results in rapid hematopoietic reconstitution, often in as little as 10 days[91]. However, primary graft failure/rejection occurs frequently with these highly T cell–depleted grafts, and a second hematopoietic stem cell infusion is often required. Ball and colleagues sought to determine whether MSCs could positively impact engraftment in haploidentical children.[92] Fourteen children underwent transplantation with HLA-disparate $CD34^+$ cells obtained from mobilized peripheral blood. A median of 21.5×10^6 $CD34^+$ cells/kg were infused. MSCs were isolated from bone marrow about 5 weeks before HSCT and expanded up to three passages. The ex vivo–expanded cells were infused, either cryopreserved or fresh, at a dose of 1 to 5×10^6 cells/kg 4 hours before the hematopoietic stem cell graft. Compared with 47 age-, sex-, and diagnosis-matched historical controls, no difference was found in the time to neutrophil recovery (12 versus 13 days) or the time to platelet (20,000/μL) recovery (10 versus 13 days). However, the time to attain a total leukocyte count of 1×10^6/μL was shorter in the MSC group (11.5 days) compared with controls (14.9 days, $P = 0.009$). More important, none of the children receiving MSCs ($n = 14$) experienced graft failure. In contrast, the graft failure rate among the controls was 15%, consistent with published experience.

One of the consistent themes of the preclinical studies is that MSCs are most beneficial at limiting doses of HSCs. This observation suggests that umbilical cord blood transplantation may be the most useful setting for MSC cotransplantation. Umbilical cord units have a threshold cell count for clinical use, since low cell doses increase the risk for graft failure (see Chapter 108). Moreover, the time to neutrophil and platelet reconstitution tends to be longer when umbilical cord grafts are used as compared with other HSC sources.

Based on this rationale, MacMillan and colleagues[93] have cotransplanted parental (haploidentical) MSCs with unrelated umbilical cord blood grafts. Eight patients underwent transplantation with an HLA-matched unrelated umbilical cord graft for a hematologic malignancy. Haploidentical MSCs were isolated from parental bone marrow obtained at the time the patient was referred for transplant and the ex vivo–expanded cells were cryopreserved for storage. MSCs, thawed immediately prior to intravenous infusion, were transplanted at a median dose of 2.1×10^6 cells/kg 4 hours before the umbilical cord blood graft. The median umbilical cord blood total nucleated cell dose was 3.1×10^7 cell/kg. All patients attained a neutrophil count of 500/μL at a median of 19 days (range, 8 to 28 days) as compared with 86% of historical control patients at a median of 30 days (range, 10 to 59 days). Six of the eight patients attached a platelet count of 20,000/μL at a median of 1.7 months (range, 1.1 to 3.2 months) compared with 79% of historical controls at a median of 2.7 months (range, 1.5 to 6.6).

Two additional studies of cotransplantation of MSCs with umbilical cord blood cells have been reported.[94,95] However, neither was able to show a statistically significant benefit of engraftment or hematopoietic reconstitution, although this may be due to the small sample size in each study.

Of note, MacMillan and colleagues showed a striking, but not significant, reduction of regimen-related toxicity and a corresponding improvement of overall survival. Thus MSCs may find their greatest application in HCT as an ancillary cell therapy to reduce regimen-related toxicity and improve overall survival without directly impacting hematopoietic recovery, consistent with the recent reports that MSCs may confer tissue protection against radiation injury.[96,97]

Three studies have used MSCs to rescue HCT patients after graft failure. Le Blanc and colleagues used MSC therapy to induce hematopoietic recovery in three patients with either primary or secondary graft failure.[98] Meuleman and colleagues rescued two of six patients,[99] and Fouillard and colleagues reported a single patient in which haploidentical MSCs stimulated autologous hematopoietic recovery after primary failure of a mafosfamide-purged autograft.[100] Collectively, these case reports suggest that MSCs may most significantly foster

hematopoietic engraftment/reconstitution under "failure" conditions. Thus MSCs may find greater value as an agent to rescue graft failure in contrast to up-front use to promote primary engraftment.

Future Applications

Before MSCs became cell therapy agents, stromal cells were used to generate long-term bone marrow cell cultures. This hematopoietic marrow cell culture methodology is being applied to clinical setting by using MSCs as a "feeder" layer to culture-expand primitive hematopoietic progenitors for transplantation to foster engraftment and promote hematopoietic reconstitution. Early results of an ongoing clinical trial at the MD Anderson Cancer Center[101] show that after double cord blood transplantation, in which 1 unit was expanded ex vivo on a monolayer of MSCs, the median time to neutrophil recovery (>500/μL) was 15 days (range, 9 to 42 days) and the time to platelet recovery (>20,000/μL) was 40 days (range 13 to 62 days). Moreover, 97% of patients attained neutrophil engraftment. Although preliminary, these data represent a marked improvement compared with standard cord blood transplantation.

Mesenchymal Stromal Cells for the Treatment of Graft-Versus-Host Disease

GVHD occurs in HCT when donor T cells recognize the patients' organs (host) as foreign and cell-mediated immune attack ensues. It is one of the most severe complications of allogeneic HCT. The immunomodulatory capacity of MSCs suggests that these cells may be effective agents for the treatment of GVHD.

Based on limited preclinical in vitro data, and without animal models, a 9-year-old boy with severe refractory gut and liver GVHD (after a peripheral blood stem cell transplant from a matched, unrelated donor) was treated with ex vivo–expanded MSCs derived from his haploidentical mother.[69] While continuing to receive prednisolone and cyclosporine, an infusion of 2×10^6 MSCs/kg led to a prompt reduction of his serum bilirubin concentration and stool output (Fig. 100-3). His cyclosporine was then discontinued to enhance a graft-versus-leukemia effect, but this led to an acute exacerbation of his gut and liver GVHD. A second infusion of MSCs (1×10^6 cells/kg) again resulted in rapid reduction of his serum bilirubin and stool output. About 18 months after the MSC infusions, the patient had recurrent GVHD, developed interstitial pneumonia, and died. Despite the unfortunate regimen-related death, this landmark report indicated the potential of MSCs to effectively treat GVHD.

Subsequently, many small studies (case series) have been published that mostly support the notion that MSCs may be effective therapy for GVHD; however, the outcomes are highly varied, possibly due to the different MSC expansion protocols and the diversity of patients and treatment schedules. Notably, growth media supplementation with fetal bovine serum or human serum platelet lysate or growth factors with or without serum may alter the immune modulatory capacity of the processed MSC product.

The largest published trial in this area is a phase II multicenter study by the European Group for Blood and Marrow Transplantation to treat steroid-resistant acute GVHD.[70] The study included 55 patients (30 adults, 25 children) with grade II ($n = 5$), III ($n = 25$), or IV ($n = 25$) disease who had failed one to five prior therapies. Patients received a median total dose of ex vivo–expanded bone marrow MSCs of 1.4×10^6 cells/kg patient body weight (range, 0.4 to 9.0×10^6) derived from HLA-identical sibling donor ($n = 5$), haploidentical donors ($n = 18$), or third-party HLA-disparate donor ($n = 69$). Of these 55 patients, 27 received 1 infusion of MSCs, 22 received two infusions, and 6 received three to five infusions, all without MSC-related toxicity. Thirty patients (55%) had a complete response, and nine (16%) had a partial response, yielding an overall response rate of 71%. HLA-matching had no effect on the response. Of note, complete responders had a lower 1-year transplant-related mortality compared with partial responders and nonresponders (37% versus 72%, $P = 0.002$) and a higher overall survival (53% versus 16%, $P = 0.018$). These data portend great use of MSCs for the treatment of GVHD; however, such remarkable results have not yet been reproduced.

The only large, randomized, double-blind, placebo-controlled phase III trial of MSC therapy of steroid-refractory acute GVHD to date was conducted by Osiris Therapeutics, Inc. The study outcome has been released to the public but not published in the peer-reviewed literature. Briefly, patients ($n = 260$, 28 children) received 2×10^6 MSCs/kg or placebo twice a week for 4 weeks. The durable complete response (primary endpoint) was not statistically different between the treatment and placebo groups (35% versus 30%), and overall survival was not improved; however, the responses specifically in the liver (76% versus 47%, $P = 0.26$) and in the gut (88% versus 64%, $P = 0.018$) were significantly improved.

MSC therapy is also being studied as a component of first-line treatment of acute GVHD. In a trial sponsored by Osiris Therapeutics, Inc., 32 patients with newly diagnosed GVHD were treated with standard corticosteroid therapy and randomized to receive either 2 or 8×10^6. Complete response was observed in 73% of all patients without a difference between the two dose groups.[102] Although these

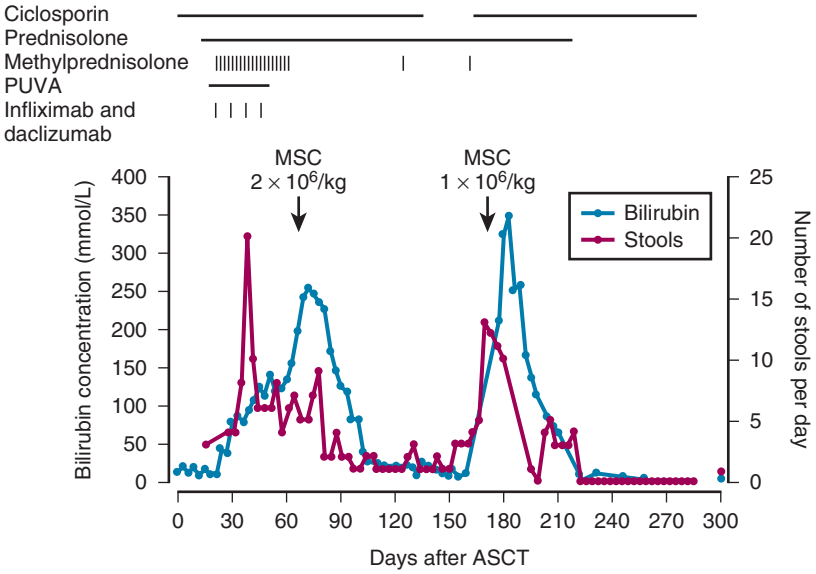

Figure 100-3 CLINICAL COURSE AND IMMUNE SUPPRESSION OF THE FIRST GRAFT VERSUS-HOST DISEASE (GVHD) PATIENT TO BE TREATED WITH MESENCHYMAL STROMAL CELLS. Pharmacologic immune suppression is indicated *(top); arrows* indicate the time of MSC infusions. *ASCT,* Allogeneic stem cell transplantation. *(With permission from Le Blanc K, Rasmusson I, Sundberg B, et al: Treatment of severe acute graft-versus-host disease with third party haploidentical mesenchymal stem cells,* Lancet *363:1439, 2004.)*

results are encouraging, randomized controlled trials are essential before any assertions can be made regarding the role of MSCs as a component of first-line therapy of acute GVHD.

Of note, the enormous interest in MSCs as treatment for GVHD originated from the report of a single-patient treatment, which took place without a supportive animal model. This sequence of events is quite fortunate for the field because the subsequently published animal data suggest that MSCs may not effectively treat established GVHD, in contradiction to the clinical findings.[103,104] This discrepancy may reflect the substantial difference between mouse and human MSCs,[16] as well as their respective immune systems.[105] Although the role of MSC therapy for GVHD remains to be completely defined, the recognition of clinical benefits warranting further randomized trials underscores the importance of initial pilot clinical trials, as opposed to relying solely on preclinical animal models, to investigate the therapeutic potential of a novel cell therapy product.

FUTURE DIRECTIONS

We are beginning to unravel the highly complex biology of MSCs that will undoubtedly foster effective clinical applications. MSCs hold great promise to facilitate hematopoiesis, as well as hematopoietic reconstitution after HCT. Additionally, MSCs clearly can modulate the immune response, despite our present inadequate understanding of the MSC immune system interaction. Moreover, novel approaches using MSCs as cell therapy in regenerative medicine are emerging.

Two overriding challenges lie ahead. First, we must better understand the mechanism of action for each therapeutic activity and design clinical trials to ensure that the best possible outcomes are being observed. Second, we must conduct numerous early-phase clinical trials to define the potential of MSCs followed by double-blind, placebo-controlled trials published in the peer-reviewed literature to first prove and then validate the clinical utility of MSCs.

CHAPTER 101

T-CELL THERAPY OF HEMATOLOGIC DISEASES

Gianpietro Dotti and Malcolm K. Brenner

Conventional modalities for treating cancer remain unsatisfactory. Despite the introduction of small molecules that target specific molecular lesions or pathways within the cancer cells, cure rates for many common tumors remain low, while adverse events are still distressingly high. Cancer immunotherapy represents a promising extension of highly targeted cancer therapy with a favorable toxicity profile and excellent pharmacoeconomics. Although most attention has been on the development of monoclonal antibodies, beneficial results with cellular immunotherapy are now being reported.[1-4] Although to date these have primarily been obtained in subjects with lymphoma, melanoma, or neuroblastoma, methodologies are being developed to allow us to extend the tumor range.

Many human tumors express tumor-specific antigens (TSAs) or tumor-associated antigens (TAAs) that can be recognized by the host immune system and induce antitumor cell-mediated and humoral immune responses.[5] Although these responses may be transient and are not always associated with clinical responses, they provide evidence for the existence of tumor-directed immunity in humans that may also have antitumor activity.[1] Several barriers block the development of more effective antitumor immunity in subjects with cancer.[6,7] First, many human tumors express few major histocompatibility complex (MHC) molecules or have poor processing of their potential tumor antigens. Even when TAAs/TSAs are processed and presented, most tumors lack the costimulatory molecules necessary to implement a long-lived and effective immune response. In addition to these passive defenses against immunity, many tumors can "edit" the immune system to their advantage, secreting cytokines such as TGFβ that directly inhibit cytotoxic effector T-cell growth, function, and survival or that favor expansion of IL-4-producing T cells (Th2 cells) or regulatory T cells (Treg) rather than effector T cells.[6] Finally, intensive chemotherapies and radiotherapies can themselves severely reduce immune function by destroying antigen-presenting cells and dividing T lymphocytes.

As our understanding of the molecular basis of tumor immune escape has increased, it has been possible to derive countermeasures that may allow us to induce more potent antitumor immune responses, and that will soon allow us to extend effective therapies to a broad range of common tumors.

TYPES OF CELLULAR IMMUNOTHERAPY

Cellular immunotherapy may be active, using cell-based vaccines derived from tumor cells themselves or antigen-presenting cells expressing TAA/TSA from proteins or peptides, or passive, by direct adoptive transfer of viable immune cells. The former approach relies on the intact afferent and efferent immune system of the host responding to the stimulus with an effective antitumor response, whereas the latter is the cellular equivalent of antibody serotherapy, in which the transferred immune cells are expected to attack the tumor cells directly, albeit with a phase of in vivo expansion, and to subsequently establish a pool of memory cells to provide long-term protection against resurgent disease. Several cell subsets are currently being studied in adoptive transfer protocols, including activated T lymphocytes, tumor-infiltrating T lymphocytes, antigen-specific cytotoxic T lymphocytes (CTLs), natural killer cells, γδ T cells, and natural killer T cells. In this chapter we discuss adoptive transfer of activated T lymphocytes and CTLs.

Adoptive Cell Therapy With T Lymphocytes

In principle, lymphocytes have the ability to traffic through multiple tissue planes and to be self-renewing. These assets, coupled with their ability to destroy tumor or viral infected target cells through a range of mechanisms, make them an appealing resource for adoptive transfer, and a multiplicity of clinical studies using this approach have now been described. Adoptive lymphocyte therapies may use allogeneic or autologous cells, which may be of tightly defined specificity (e.g., T-cell clones) or broad phenotype and activity (e.g., tumor-infiltrating lymphocytes). As we have learned more about the molecular basis of immune recognition and immune regulation, it has become possible to genetically modify the infused lymphocytes to alter their specificity or behavior. In this section we describe examples of each type of adoptive transfer and discuss the relative merits and limitations of each.

Donor Lymphocyte Infusion

It has long been apparent that the curative effects of allogeneic stem cell transplants for many hematologic malignancies can be attributed to a graft-versus-leukemia (GVL) effect largely mediated by the incoming T cells within the donor graft. Thus patients with chronic graft-versus-host disease (GVHD) were well recognized as having a lower probability of relapse than individuals without this unpleasant complication. Similarly, recipients of syngeneic grafts have the lowest rate of GVHD and the highest risk for relapse. In 1990, Kolb et al[8] took advantage of this observation and deliberately infused donor lymphocytes in an attempt to eliminate recurrent disease in patients with chronic myeloid leukemia (CML). Their positive results have been confirmed in multiple studies worldwide, and remission can be induced in over 80% of patients with Epstein-Barr virus (EBV) lymphoma and in more than 50% of CML patients who relapse after transplantation by stopping immunosuppressive treatment or infusing donor lymphocytes.[9] Unfortunately, donor lymphocyte infusion (DLI) is much less effective at treating other types of relapsed leukemias after transplantation, with a 29% remission rate for acute myeloid leukemia and only 5% for acute lymphoblastic leukemia.[10] It is not clear why these differences occur, because all these leukemias present the minor histocompatibility antigens that are likely the targets of this GVL effect, although many minor histocompatibility antigens have yet to be defined. DLI therapy may also produce severe adverse effects, because the frequency of broadly alloreactive effector cells is usually much higher than the frequency of lymphocytes targeted exclusively to the relapsed malignancy. As a consequence, patients receiving DLI often develop GVHD. This complication may be manifested by skin, gut, or liver damage or by pancytopenia if there is significant residual host hemopoietic chimerism. Strategies aimed at retaining the benefits of GVL while preventing GVHD have included the depletion of alloreactive T cells in the donor lymphocyte

product and the incorporation of suicide genes into the infused donor T cells so that they may be killed if the GVHD activity exceeds the benefits from GVL.[11] Ultimately, investigators may wish to identify tumor-restricted target antigens on the malignant cells and infuse antigen-specific T cells directed to them.

Infusion of Activated T Lymphocytes

When T cells are polyclonally stimulated, for example by simultaneously cross-linking their CD3 and CD28 receptors by CD3/CD28 monoclonal antibodies on beads, then the cells proliferate. They also secrete tumoricidal cytokines such as tumor necrosis factor-α and can mediate MHC-unrestricted cytotoxicity toward a range of tumor target cells. Efforts have been made to harness these effects by producing large numbers of CD3/CD28-activated T cells for cancer patients and infusing them. Although infusion of CD3/CD28-activated T lymphocytes after autologous stem cell transplant may improve patients' T-cell reconstitution, as yet there is no evidence to suggest improved antitumor activity.[12] In current studies, adoptive therapy is being combined with vaccination with tumor antigens such as the human telomerase reverse transcriptase and the antiapoptotic protein survivin to enhance antitumor activity.[12] Activated T lymphocytes that are additionally primed with interferon-γ and IL-2 (so-called cytokine-induced killer cells) may have superior clinical potential for hematologic malignancies.

Adoptive Immunotherapy With Virus-Specific Cytotoxic T Lymphocytes

Viral infections are one of the commonest causes of morbidity and mortality after stem cell transplant and are more prevalent as the degree of antigen mismatching between donor and recipient is increased. The most common problematic viral infections after stem cell transplant are reactivated herpesviruses, including cytomegalovirus (CMV), which typically causes pneumonitis and hepatitis, and the γ-herpesvirus EBV, which may cause a rapidly fatal lymphoproliferative disease (LPD). In children and recipients of cord blood transplants, adenoviral disease is also common. Adoptive transfer of virus-specific T cells appears to effectively prevent and treat these infections after transplant. Infusion of even small numbers of specific cells (10^6 or less) may be sufficient for benefit, because the lymphodepletion of the immediate posttransplant period is associated with the release of homeostatic cytokines such as IL-7 and IL-15, which augment the expansion of virus-specific T cells when they encounter their antigen.

Donor-Derived Virus-Specific Cytotoxic T Lymphocytes

Walter et al[13] pioneered the use of CMV-specific $CD8^+$ T-cell clones to prevent CMV reactivation in allogeneic hematopoietic stem cell transplant (HSCT) recipients. They activated and expanded donor-derived CTL by coculture with CMV-infected autologous fibroblasts. Neither viremia nor disease activation were detected in any of the treated patients. However, CMV-specific CTL clones did not persist unless there was also recovery of endogenous $CD4^+$ T cells.

We reported the use of donor-derived polyclonal but EBV-specific CTLs to treat and prevent EBV-associated LPD after allogeneic HSCT.[14] Since 1993, over 110 stem cell recipients have received donor-derived EBV-specific CTLs. None of the patients in our prophylaxis group developed posttransplant lipoproliferative disorder, in contrast to an incidence of 11.5% in 44 patients in the control group. Elevated EBV-DNA levels declined within 1 to 3 weeks of first T-cell infusion, and EBV-specific CTLs have also been found effective in 10 of 12 patients with bulky EBV-associated lymphoma. Other groups have confirmed that adoptive immunotherapy with EBV-specific CTLs effectively prevents and treats EBV-LPD after hematopoietic stem cell or solid organ transplant. Improvements in methodology to simplify and accelerate manufacture of these viral-specific CTLs have followed. We have developed a culture method to generate, in a single culture, CTL lines that have antiviral activity for EBV, CMV, and adenovirus and minibioreactors in which to prepare these cells in a closed system.[15] In combination, these techniques allow us to make sufficient CTLs for patient treatment in less than 10 days instead of more than 10 weeks. Other groups have developed even faster techniques, in which T cells activated by viral antigens are selected by columns specific for activation markers such interferon-γ.[16]

Third-Party Allogeneic Virus-Specific Cytotoxic T Lymphocytes

Ideally, virus-specific CTLs should be immediately available from a cryopreserved line. The cost of doing this for each patient at risk is prohibitive, but Haque et al[17] generated a bank of polyclonal EBV-specific CTLs expressing common human leukocyte antigens (HLAs) and gave the best-matched cells to subjects who developed EBV lymphoproliferation after solid organ transplant. More recently they reported results of a phase II multicenter trial in which they treated 33 patients with EBV-LPD with an overall response rate of 64% at 5 weeks and 52% at 6 months. These impressive results have led us to develop a similar multicenter study to evaluate whether these trivirus-specific CTL lines may have similar activity against EBV, CMV, and adenovirus in partially HLA-matched allogeneic patients. The interim analysis of this study confirmed a greater than 80% rate of infection control in 45 recipients of allogeneic stem cell transplant with intractable EBV, CMV, or adenovirus infections.

Adoptive Immunotherapy of Viral-Related Malignancies

The encouraging results of adoptive immunotherapy with EBV-specific CTLs in the immunocompromised host led us to extend this strategy to other EBV-associated tumors (lymphoma and nasopharyngeal cancer) that develop in the immunocompetent subject. Unlike EBV-LPD, which expresses the highly immunogenic viral latency antigens EBV nuclear antigen 1 (EBNA1), EBNA2, and EBNA3, these other EBV tumors express a limited number of poorly processed (EBNA1) or weakly stimulatory (latent membrane protein 1 [LMP1] and LMP2) EBV-derived antigens. We have therefore used CTLs specific for these EBV antigens, beginning with the cells directed to LMP2. The CTLs were generated from patients with Hodgkin disease by using dendritic cells that are engineered to overexpress LMP2. The infusion of polyclonal LMP2-specific T cells containing both $CD4^+$ and $CD8^+$ T cells increases LMP2-specific T-cell responses and lead to complete tumor regression in 8 of 12 patients with EBV-positive lymphoma.[2]

Similar results have been obtained in EBV-associated nasopharyngeal carcinoma (NPC), a tumor that originates from the epithelial cells of the nasopharynx.[18] Like EBV-associated lymphomas, NPCs express the same restricted set of weakly immunogenic viral antigens, including EBNA1, LMP1, and LMP2. Treatment of EBV-positive NPC with polyclonal EBV-specific CTLs has produced complete clinical responses in patients with limited tumor burden.[18] One of the main limitations of treatment of NPC with EBV-specific CTLs is the failure of in vivo expansion of adoptively transferred cells. Thus infusions of these cells may best be given immediately after lymphoreductive chemotherapy, enabling their expansion to be supported by the increased availability of homeostatic cytokines. Alternatively, these cells could be engineered to enhance their "survival" in vivo as discussed in Genetic Modifications of T Cells.

Adoptive Immunotherapy of Non–Viral-Mediated Malignancies

Many different types of tumor-associated or tumor-specific antigens have been described and are reviewed in a National Cancer Institute

initiative to prioritize cancer antigens.[5] Among the most widely studied are the tumor testis antigens, which are expressed by a range of tumors, including melanoma. For example, CTL clones specific for melanoma Ag recognized by T cells (MART) have been successfully used to treat patients with metastatic melanoma.[1] Although infused CTLs localized to tumor sites and induced clinical responses, tumor antigen–loss variants were observed in three patients who subsequently relapsed, highlighting the risk for escape mutants when a single clone of CTLs targets a single epitope. In the allogeneic transplant setting ex vivo–expanded donor-derived CTLs have also shown antileukemia activity when directed at minor antigens, although off-target toxicity was observed due to the unexpected presence of the target antigens on lung tissue.[19]

GENETIC MODIFICATIONS OF T CELLS

There is considerable interest in genetically modifying T cells so that they may be used for cancer therapy. Early clinical studies used genetic modification to "mark" the T cell infused so that these cells can be detected by polymerase chain reaction amplification in the peripheral blood or other tissues.[14] More recently, efforts have been devoted to "redirecting" the antigen specificity of T lymphocytes. Most TAAs are self-proteins to which the immune system has limited responsiveness, because of the development of tolerance by clonal deletion or anergy. Hence tumor antigen–specific T cells isolated from patients with cancer may have low-affinity T-cell receptors (TCRs), limiting their cytotoxic activity against tumor cells. Investigators have overcome this limitation by expressing transgenic TCR α- and β-chains of high affinity[20] or by expressing a synthetic chimeric antigen receptor (CAR)[21] that has the binding domains of, for example, a monoclonal antibody, and the endodomains of the T-cell receptor to ensure signaling and T-cell activation once the CAR has been engaged (Fig. 101-1). Finally, interest in genetic modification of T cells has also arisen as a means of incorporating countermeasures to the multiplicity of immune evasion strategies used by potentially immunogenic tumor cells or to enhance the "survival" of T cells in vivo[22] (see Fig. 101-1). Because T lymphocytes can be long-lived cells and may proliferate extensively in vivo, most gene transfer studies have used integrating vectors such as γ-retroviral vectors, lentiviral vectors, or transposon/transposase integrating plasmids.

T Lymphocytes and Gene-Marking Studies

Incorporation of a marker gene in T cells was the first authorized human gene transfer study.[23] In subsequent studies, tumor-infiltrating T lymphocytes and antigen-specific CTLs were transduced with retroviral vectors coding for the neomycin resistance gene (neo) or for a nonfunctional human receptor such as the truncated form of the p75 low-affinity nerve growth factor receptor (LNGFR). These studies indicated that adoptively transferred T cells and antigen-specific CTLs could persist and recirculate for more than 10 years in the peripheral blood.[14] Gene-marked tumor antigen–specific CTLs were also able to reach the tumor microenvironment. There were no adverse events attributable to gene transfer. There are now extensive efforts to develop technologies that will allow more sophisticated in vivo analyses in real time of functional transgenes (such as the thymidine kinase gene) expressed by adoptively transferred T lymphocytes, allowing evaluation of their temporospatial distribution.

Artificial αβ-T-Cell Receptors

The large-scale culture of T lymphocytes to enrich the scanty precursors specific for weak TAAs is often unsuccessful and always tedious. This process can be bypassed by introducing additional TCR genes with predetermined specificity for the weak tumor antigen into a polyclonal population of T cells. Technical improvements in retroviral transduction mean that 30% of polyclonal T lymphocytes can now be induced to express a transgenic TCR for TAAs, including MART1, melanoma antigen (MAGE)3, MDM2, and WT1, for minor histocompatibility antigens such as HA1, and for infectious agents such as human immunodeficiency virus type 1 (HIV-1) and EBV.

Polyclonal T cells expressing transgenic MART1-specific αβ-TCRs have been safely infused in patients with metastatic melanoma after lymphodepleting chemoradiotherapy.[20] Up to 30% of these patients had objective regression of metastatic disease. Similar results have been obtained in patients with metastatic synovial cell sarcomas and melanoma who were given T cells expressing an NY-ESO-1–specific αβ-TCR. Although most of these patients had no severe adverse events, toxicity was observed in patients with metastatic colon carcinoma who received T cells expressing a TCR directed to the carcinoembryonic antigen,[24] due to T cell–mediated damage to

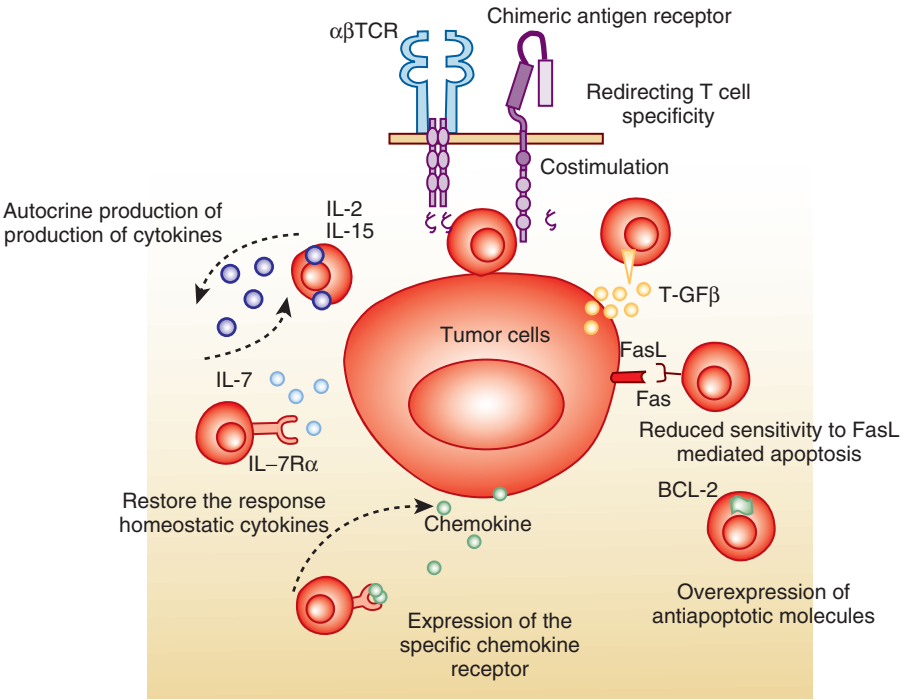

Figure 101-1 GENETIC MODIFICATIONS OF T LYMPHOCYTES FOR ADOPTIVE T-CELL THERAPY. *TCR,* T-cell receptor.

normal gastrointestinal epithelial cells expressing low levels of the target antigen. Thus T cells with high-affinity transgenic TCR may produce "on-target" but "off-organ" toxicities to normal tissues that physiologically express the target antigen at low level. The first TCR gene therapy trial for patients with acute leukemia targeting WT1 is currently recruiting patients.

A major problem of TCR gene transfer is the resulting "cross pairing" between transgenic α- or β-receptor chains and the reciprocal endogenous TCR α- and β-chains, to create loss of function or—and potentially worse—gain of function receptors that may produce autoimmune disease. Although such adverse effects have been elegantly demonstrated in mouse models, human clinical trials have not yet revealed such issues. Investigators have developed several molecular strategies intended to modify the transgenic TCRs to make them less likely to cross pair or to silence the endogenous TCRs.

Chimeric Antigen Receptors

The cytotoxic activity of T cells through their native or transgenic TCR is MHC restricted so that multiple distinct transgenic αβ-TCRs would be required to recognize tumor antigens associated with the multiple MHC polymorphisms in a human population, precluding a "universal" receptor. In addition, tumor cells can downregulate MHC molecules and avoid immune recognition by conventional TCRs. In an attempt to overcome this limitation, MHC-unrestricted artificial CARs have been generated.[25] CARs are usually generated by joining the light and heavy chain variable regions of a monoclonal antibody expressed as a single-chain Fv (scFv) molecule to the transmembrane and cytoplasmic signaling domains derived from CD3ζ-chain or Fc receptor γ chain through a flexible spacer. Thus they combine the antigen specificity of an antibody and the cytotoxic properties of a T cell in a single fusion molecule. Because CARs bind to target antigens in an HLA-unrestricted manner, they are resistant to many of the tumor immune evasion mechanisms, such as downregulation of HLA class I molecules or failure to process or present proteins, used by tumor cells to escape immune attack. First-generation CARs, incorporated the cytoplasmic region (endodomains) from the CD3ζ or the Fc receptor γ chains as their signaling domain.[21] Although these receptors successfully redirected T-cell cytotoxicity, they failed to stimulate T-cell proliferation and survival in vivo, likely because of the lack of appropriate costimulatory signals to T cells following engagement of the CAR. Hence the efficacy of these first-generation CAR T cells has been modest in phase I clinical trials in patients with lymphoma or ovarian cancer. Second-generation CARs were constructed by incorporating signaling domains from costimulatory molecules such as CD28, OX40, and 4-1BB within the endodomain.[26] This improved antigen-specific T-cell activation and expansion as tumor cell engagement of second-generation CARs alone is sufficient to provide costimulation. Thus the incorporation of the CD28 endodomain within a CAR specific for the B cell–associated antigen CD19 enhances the in vivo expansion of T lymphocytes that express this CAR and produced complete responses in lymphodepleted patients with CD19-positive malignancy.[27] A similar study in which a different costimulatory endodomain (4-1BB) was incorporated into the CD19-specific CAR produced even more striking expansion of the CAR-CD19 T cells in vivo and the apparent eradication of both normal and malignant B cells in two of three patients with B-cell chronic lymphocytic leukemia, implying greater potency.[4] As yet we do not know the best costimulatory endodomain(s) to use or whether the optimum choice will be affected by the nature of the target antigen and tumor to which the CAR is directed.

An alternative approach to the incorporation of costimulatory endodomains within the CAR is to express CARs in antigen-specific T cells, which will then also be activated and expanded through engagement of their native αβ-TCR by professional antigen-presenting cells, with attendant costimulation. As a proof of principle we engineered EBV–specific CTLs with a CAR specific for the disialoganglioside antigen GD2a expressed by neuroblastoma cells and infused these cells in EBV-positive patients with neuroblastoma. We found that engineered EBV-specific CTL had better in vivo persistence compared with polyclonally activated T cells engineered with the identical CAR and could be associated with tumor responses, including complete remissions in 3 of 11 patients.[3] Progression-free survival correlated with persistence of CAR T cells.

Engineering T Cells to Overcome Immune Evasion Strategies

One of the main challenges to effective adoptive T-cell therapy is the lack of in vivo expansion and maintenance of ex vivo–manipulated, adoptively transferred T cells because of various tumor-induced immune evasion mechanisms. Gene transfer technologies allow us to modify T cells and restore their functionality in a hostile environment. Table 101-1 and Fig. 101-1 summarize some of the evasion strategies and genetic T-cell modification to counter them that have been described to date. For example, many tumor cells or their associated stroma produce TGFβ, which favors the development of immune tolerance and T-cell anergy, inducing effector T cell growth arrest with induction of Treg cells. Zhang et al[28] demonstrated that transfection of a dominant negative form of TGFβRII (dnTGFβRII) improved the persistence of T cells and that infusion of modified cells eliminated tumor in a mouse prostate cancer model. Subsequently investigators showed that antigen-specific T cells expressing dnTGFβRII were resistant to the antiproliferative effects of TGFβ and retained their effector function in vivo, and such TGFβ-resistant T cells are currently being studied in patients with EBV-associated lymphomas.[29] T cells may also be modified to express cytokine or cytokine receptor genes that mimic the milieu found during lymphoid regeneration and restoration of homeostasis, such as IL-2, IL-7, or IL-15.[22] Although these approaches are effective in preclinical models, we do not know yet how safe or effective these transgenic cytokines and their receptors will be in clinical trials. Other genetic modifications can modulate T-cell survival and apoptosis or render antigen-specific T cells resistant to immunosuppressive drugs and may also enhance the persistence and effectiveness of T-cell therapies.

Table 101-1 Causes of Immunocompromise in Cancer Patients

IMMUNOSUPPRESSION INDUCED BY TUMOR
Antigen-specific $CD4^+$/$CD8^+$ T-cell tolerance
Defective proximal TCR signaling (decreased expressions of CD3δ chain, $p56^{lck}$, $p59^{fyn}$ tyrosine kinases)
Impairment of antigen-processing machinery (TAP, LMP2, LMP7) or downregulation of MHC molecules and costimulatory molecules
Activation of negative costimulatory signals (CTLA-4, PD-1, B7-H4, BTLA)
Tumor-derived immunosuppressive cytokines (TGFβ, IL-10, VEGF, PGE_2)
Expression of immunomodulatory or proapoptotic molecules by tumor (tryptophan-depleting enzyme IDO, galectin-1, FasL, TRAIL)
Recruitment and expansion of immunosuppressive cell populations (regulatory T cells, myeloid/plasmacytoid dendritic cells)
IMMUNOSUPPRESSION INDUCED BY THERAPY
Neutropenia, depletion and functional impairment of monocytes
Hypogammaglobulinemia (decreased levels of IgA and IgM)
Defective T cell–mediated immune response

T Lymphocytes and Transfer of Safety Genes

A major problem of any successful cell therapy is that adverse events produced by the infused cells may persist and worsen if the cells survive and proliferate. A classic example is the GVHD that occurs when allogeneic donor T cells are transferred with the hemopoietic graft. It is also clear, however, that even nonalloreactive T cells may cause serious and even lethal toxicities, particularly if they are genetically modified to target highly expressed self-antigens present on both tumors and normal tissues. Similarly, efforts to enhance the survival and expansion of T cells may lead to uncontrolled expansion of the manipulated T cells, an event that may even occur as a result of retroviral genotoxicity alone. Although malignant transformation has so far been observed only in clinical studies of hemopoietic stem cells transduced by murine oncoretroviral vectors,[30] there is understandable concern that it can potentially occur after the transfer of gene-modified T cells. For all these reasons there has been increasing interest in the incorporation of safety switches or suicide genes in any T cell that is adoptively transferred to humans.

Safety or suicide genes have been best studied in the recipients of DLI in patients with hematologic malignancies relapsed after allogeneic HSC transplantation in order to prevent the occurrence of GVHD. Adequate doses of donor T cells can be safely given only if there is some means by which unwanted alloreactivity can be abrogated in vivo. Over the past 10 years efforts have been made to achieve this aim by genetically modifying T cells through the introduction of suicide genes, of which the herpes simplex thymidine kinase (HSVtk) is the most popular and advanced in term of clinical development, because it is currently in a Phase III clinical trial.[11] HSVtk phosphorylates specific nucleoside analogues, including ganciclovir, to nucleoside monophosphates. These compounds block effective DNA synthesis and kill dividing cells. In several clinical trials this gene has been transferred to donor T lymphocytes, which have then been given to the allogeneic stem cell transplant recipient to prevent or treat relapse.

The approach has had some success. HSVtk gene–modified T cells persist in the circulation in most of the patients and are removed after the administration of ganciclovir, often with an improvement in GVHD.[11] However, several problems remain. HSVtk is a viral protein, and in some patients a cell-mediated immune response against HSVtk is detected, causing undesired premature elimination of transgenic cells. Other drawbacks of HSVtk include the unintended elimination of gene-modified cells when ganciclovir is used for treatment of CMV reactivation, ganciclovir resistance that may occur from truncated HSVtk generated from cryptic-splice donor and acceptor sites, and slow elimination of transgenic cells because HSVtk requires DNA synthesis to be active; such delayed activity may be undesirable if T cells are acutely toxic.

Investigators attempted to overcome some of these limitations by developing new suicide genes based on human molecules that are potentially less immunogenic. T cells expressing human CD20 can be theoretically rapidly eliminated by the infusion of anti-CD20 monoclonal antibodies. Other suicide genes are based on chimeric molecules derived from human proteins that are involved in the apoptotic pathway and modified to be activated by a small molecule (inducible Fas and inducible caspase 9). These inducible molecules activate apoptosis, which produces rapid cell death.

A clinical study has used iCasp9, which consists of the sequence of the human FK506-binding protein (FKBP) with an F36V mutation, connected to human caspase 9 deleted for its endogenous activation and recruitment domain.[31] FKBP12-F36V binds with high affinity an otherwise bioinert small-molecule dimerizing agent (AP1903). In the presence of the drug, the iCasp9 promolecule dimerizes and activates the intrinsic apoptotic pathway leading to cell death. To ensure the suicide gene is expressed in all the infused cells, the construct incorporates a selectable marker gene (CD19). The study infused donor-derived iCasp9 T cells after haploidentical stem cell transplant and if patients developed GVHD, administered a single dose of the dimerizing drug. The investigators observed rapid destruction of more than 95% of the cells with prompt resolution of GVHD.[31]

FUTURE DIRECTIONS

With the approval of the first cell therapeutic for cancer (Dendreon), and the publication of increasing numbers of reports of complete tumor responses after cellular immunotherapy, there is increasing hope that this methodology will finally take its place among other more conventional cancer therapeutics. In addition, the combination of T-cell therapies with agents such as antibodies to T-cell check-point molecules (including CTLA-4[32] and anti-PD-1[33]) that block the immunosuppressive mechanisms of the tumor environment may further increase the clinical potency of T-cell therapies. Much remains to be done to ensure the effectiveness and safety of these cell therapies and to develop economic models to support their development to licensure, but we are confident that well within the next decade this approach will cease being almost entirely experimental and will be considered a significant component of standard cancer therapy.

CHAPTER 102

NATURAL KILLER CELL-BASED THERAPIES

Sarah Cooley, Michael R. Verneris, and Jeffrey S. Miller

The antileukemia effect of allogeneic hematopoietic cell transplantation (allo-HCT) is mediated through both high-dose chemotherapy and immune reactions. Reduced intensity regimens still provide significant protection from relapse, supporting the notion that allogeneic immune effectors can control or eradicate leukemia (or both). Exactly which cell populations account for this graft-versus-leukemia (GVL) effect is not entirely established and may vary among individuals and diseases. Immune cell populations can be mechanistically divided into two broad categories, the innate (natural killer [NK] cells and antigen-presenting cells [APCs]) and adaptive (T cell and B cells) arms of the immune system. Whereas developmentally mature innate immune cells are able to perform their biologic functions, adaptive immune cells generally require antigen presentation, activation, and expansion before they can act. These paradigms are changing. It is becoming increasingly clear that NK cells are capable of memory responses, a function previously ascribed only to the adaptive immune system. Likewise, it appears that adaptive cells can mediate major histocompatibility complex (MHC) unrestricted killing, typically considered a quality of the innate system. Importantly, for optimal function, cells from both arms of the immune system work in concert with other immune cells. Because the antitumor efficacy of conventional cytotoxic agents is limited by off target toxicity and resistance, cell-based therapies provide an attractive alternative. Progress in cytokine biology and improved techniques to separate, expand, and purify cells have transformed the concept of cell-based therapy into a reality. This chapter examines characteristics of innate NK cells and discusses how they may be manipulated to combat infection and treat malignancy, both in transplant and nontransplant settings.

NATURAL KILLER CELL BIOLOGY

Natural killer cells were first functionally recognized in 1975 for their ability to lyse virally infected and tumor targets without prior sensitization. NK cells comprise 10% to 15% of the peripheral blood (PB) lymphocyte pool in normal humans, but they are also found in the bone marrow (BM), spleen, liver, lymph nodes, lungs, and pregnant uterus (Fig. 102-1). Defined phenotypically by the expression of CD56 or NKp46 and a lack of a CD3/T-cell receptor complex, they develop from BM-derived progenitors via distinct developmental stages in secondary lymphoid tissue (SLT)[1] (see Chapter 20). Mature NK cells can be functionally distinguished by CD56 density. The $CD56^{dim}$ subset exhibits potent natural cytotoxicity (killing of class I negative targets) and displays Fc receptors (CD16) that trigger potent activating signals after recognition of immunoglobulin-coated targets, a process called *antibody-dependent cellular cytotoxicity* (ADCC). $CD56^{dim}$ cells also produce cytokines in response to targets or activating receptor ligation. In contrast, $CD56^{bright}$ NK cells are more proliferative and are less cytotoxic. $CD56^{bright}$ cells respond to inflammatory cytokines (interleukin-2 [IL-12], IL-15, and IL-18) to rapidly produce large amounts of interferon-γ (IFN-γ). NK cells also proliferate and become activated in response to IL-2, IL-15, and IL-21. IL-15 is of particular importance for NK cell homeostasis. Transpresentation of IL-15 by IL-15Rα on dendritic cells (DCs) appears to be the physiologic source of cytokine leading to NK activation.[2] Although these cytokines enhance CD56 receptor density on activated cells, they should not be confused with the unique functional properties of steady-state $CD56^{bright}$ cells.

Natural Killer Cell Functions

Natural killer cells provide a link between the innate and adaptive immune systems[3] and play an important role in immune surveillance, pregnancy outcomes, and response to infections (see Fig. 102-1). NK cell function can be divided into seven separate activities that include interaction with autologous DCs, activation, expansion, homing to malignant or virally infected targets, direct cell–cell killing, cytokine production, and eradication of allogeneic DCs. These responses may differ based on the stimulus and the NK cell subset studied. Activated NK cells produce (and often respond to) cytokine and chemokines, including IFN-γ, tumor necrosis factor (TNF), and transforming growth factor β (TGF-β). NK cells express β2 integrins such as LFA-1 and CD2, which bind to molecules such as intercellular adhesion molecule 1 (ICAM-1) and LFA-3. Engagement of other NK activating receptors induces target cell apoptosis via Fas ligand (FasL) and TNF-related apoptosis inducing ligand (TRAIL) pathways or by releasing perforin and granzyme into a small area between the NK cell and the target cells (called the *immune synapse*). These activated NK cells then produce cytokines. It is not completely known whether cytokine production or direct cell killing is physiologically most important for a therapeutic antitumor and antiinfection response. It may be that both functions are required for efficacy.

Natural Killer Cell Receptors

The ability of NK cells to respond to a wide array of targets is regulated by a complex network of surface proteins that comprise the NK receptors (NKRs). These receptors can mediate either activating or inhibitory signals. A recurring theme is that many of these receptors are MHC class I specific. Engagement of MHC class I results in a *reduction* in NK cell function. Thus, recognition of MHC class I, which is ubiquitously expressed by healthy tissues, leads to NK cell tolerance. In contrast, the loss of MHC class I, which occurs during the process of viral infection and malignant transformation, leads to the *lack* of engagement of these inhibitory receptors and in turn permits activation of the NK cell via other receptor–ligand interactions.

Killer Immunoglobulin-like Receptors

The killer immunoglobulin-like receptor (KIR) gene cluster, located on chromosome 19q13.4, encodes for 16 different type I transmembrane molecules in the immunoglobulin (Ig) superfamily. KIR genes contain either two or three extracellular domains (2D or 3D), a transmembrane region and an intracellular domain that is either long (containing inhibitory motifs) or short (containing docking sites for activating molecules). Individuals vary in the number of KIR genes that they have in their genome, and their "KIR content" can be

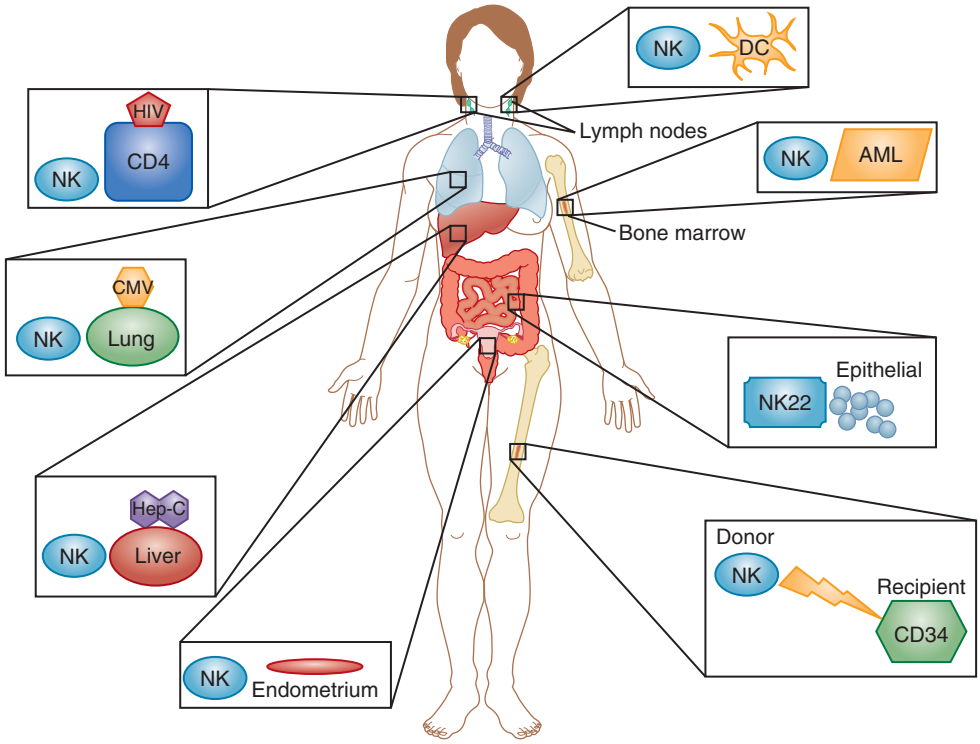

Figure 102-1 ROLES OF NATURAL KILLER (NK) CELLS IN CANCER AND HEALTH. The roles of NK cells in both health and cancer are depicted. NK cells play a critical role in initiation of immune responses by interacting with dendritic cells (DCs), resulting in reciprocal activation of both cell types (i.e., NK cells activate DCs and vice versa). NK-induced DC activation likely also results in the initiation of adaptive immune responses by inducing DCs to present antigens to T cells. Activated NK cells can go on to destroy malignant tissues, including leukemia. In the setting of allogeneic transplantation, NK cells can eradicate recipient stem cells, thereby facilitating allogeneic stem cell engraftment. Emerging data show that a subpopulation of NK cells or similar cells (known as NK22 cells, innate immune effector cells, or lymphoid tissue inducer cells) produce interleukin-22 (IL-22) and interact with lymph node stroma to mediate mucosal immunity and may accelerate immune responses after transplantation. A unique population of uterine NK cells is responsible for the maintenance of pregnancy. Still other roles for NK cells include the surveillance for and response to infectious organisms, including hepatitis virus C, cytomegalovirus (CMV) and human immunodeficiency virus (HIV). *AML,* Acute myeloid leukemia.

simplified into two haplotypes. Each haplotype contains three framework genes (*KIR3DL3, KIR2DL4,* and *KIR3DL2*) and a variable number of activating and inhibitory genes from the centromeric (Cen) or telomeric (Tel) ends of the gene locus. KIR A haplotypes contain five inhibitory receptors (2DL1, 2DL3, 3DL1, 3DL2, and 3DL3) and just one activating receptor (2DS4). KIR B haplotypes contain a variable number of genes but have more activating KIR than A haplotypes.

Inhibitory KIRs bind to self-class I HLA molecules on potential target cells. This interaction suppresses the NK cell effector responses. Inhibitory KIRs recognize polymorphisms of HLA-C and B in a biallelic manner (i.e., C1 vs. C2 and Bw4 vs. Bw6). KIR2DL1, KIR2DL2/KIR2DL3, and KIR3DL1 bind HLA class I C2, C1, and Bw4 alleles, respectively. New data demonstrate the complexity of these inhibitory receptor–ligand interactions because the mere expression of the receptors does not predict the cellular response. The affinity of a given KIR seems to depend on allelic polymorphisms of the individual KIR itself, as well as polymorphisms of the MHC class I protein to which it binds. In some cases, these binding rules are not absolute because KIR2DL2 can bind both HLA-C1 and C2 alleles. Although KIR binding to HLA-A is controversial, some HLA-A alleles (A3 and A11) contain the Bw4 epitope, and some HLA-A alleles in the context of peptide can bind KIR3DL2. Complicating our understanding of the KIR system is the fact that the natural ligands for activating KIR remain unknown. Although some bind MHC molecules at low affinity, it is not known whether MHC functions as the natural ligands in vivo.[4]

Additional Natural Killer Cell Receptors

Several other families of activating and inhibitory receptors influence NK cell function. Some of these bind HLA molecules. The NKG2 family of C-type lectin receptors that heterodimerize with CD94 may be either inhibitory (NKG2A) or activating (NKG2C) and can recognize nonclassical HLA-E. NKG2D does not heterodimerize with CD94 and recognizes stress-induced molecules such as MHC class I polypeptide-related sequence A/B (MICA and MICB) or viral-derived proteins such as the cytomegalovirus (CMV)-related UL binding proteins (ULBP1-6).[5] Additional receptors include the natural cytotoxicity receptors (NCR) NKp30, NKp46 and NKp44, DNAM-1, and Nectin-2 (CD122), 2B4, Ig-like (ILT) receptors, and leukocyte-associated immunoglobulin-like receptor-1 (LAIR-1).[6] These activating receptors are believed to play a role in communication between NK cells and DCs as well as determining whether an NK cell can recognize a target.

Natural Killer Cell Education—The Acquisition of Function, Self-Tolerance and Alloreactivity

A mechanistic explanation for the phenomenon of "hybrid resistance" and "missing self" is derived from the characterization of NK cell inhibitory receptors that recognize self MHC class I.[9,10] In both instances, because they fail to engage inhibitory receptors, target cells lacking self MHC class I expression are sensitive to NK-mediated

killing. Thus, NK cells detect either allogeneic cells or disease-associated loss of MHC class I on virally infected or tumor cells.[11] The process by which signals mediated through inhibitory receptors allow NK cells to acquire cytotoxic and cytokine producing functions has been referred to as *NK cell education* or *NK licensing*.[12,13] It has been demonstrated that NK cells lacking both KIR and NKG2A are hyporesponsive and that they cannot become educated until inhibitory receptors are expressed. Importantly, NK cell education may not be fixed. For instance, adoptive transfer of NK cells from β2-microglobulin knock-out mice (that lack MHC class I) into wild-type mice leads to education and an associated gain of function. Conversely, adoptive transfer of fully functional NK cells from wild-type mice into β2-microglobulin knock-out hosts leads to NK hyporesponsiveness.[14,15] Collectively, these data support the model of NK cell education as a dynamic, inherently plastic process in which low-level, tonic interactions may be needed to maintain cytotoxic capacity. It has also been demonstrated that the cumulative strength of inhibitory receptor signaling correlates with functional thresholds. This model, aptly compared with a "rheostat," permits self-tolerance in the normal state and allows for enhanced sensitivity to damage to healthy cells through class I downregulation.[16] Importantly, it must be emphasized that not all acquisition of NK cell function is through NK cell education. NK cells can overcome rules of NK cell education when stimulated by exogenous cytokines or cytokines induced by inflammation. In mice, the importance of inflammation-induced cytokine production leading to enhanced NK function is clearly demonstrated by the ability of NK cells from β2-microglobulin knock-out mice, which are hyporesponsive in vitro to clear murine CMV. In summary, NK education determines the function of NK cells at steady state, but other factors may overcome or even dominate, especially in the setting of disease or when cytokine-stimulated NK cells are adoptively transferred.

Natural Killer Cell Recognition of Tumors

Although the antitumor efficacy of NK cells has been most evident for myeloid malignancies, a wide variety of solid tumors, including breast, ovarian, hepatocellular, colon, neuroblastoma, Ewing sarcoma, rhabdomyosarcoma, and melanoma, are also sensitive to NK cell lysis. The relative resistance of some tumors may be attributable to a higher expression of class I HLA, which inversely correlates with the susceptibility of primary pre-B cell acute lymphoblastic leukemia (ALL) blasts to NK cell lysis.[17] Successful destruction of a target requires co-engagement of NK cell receptors by both inhibitory and activating signals. Accordingly, activating receptors such as NKG2D play an important role in immune surveillance and killing of acute myeloid leukemia (AML) stem cells. Other tumor ligands that correlate with responsiveness to NK cell–mediated killing include DNAM-1 on MDS blasts; CD137 ligand on AML targets; and B7-H3, which protects neuroblastoma from NK lysis. When considering therapeutic uses of NK cells and interventions such as the use of anti-KIR antibodies to promote tumor lysis, it is important to remember that approximately half of NK cells circulating in the PB lack KIR. Therefore, maximum killing of targets such as leukemia blasts may require blockade of other inhibitory receptor interactions, such as NKG2A and LIR-1.

Interleukin-22–Producing Tissue Resident Natural Killer Cells

Mature NK cells arise from progenitors that progress through an orderly series of developmental intermediates, defined as stages I through V on the basis of phenotype and function. Very early human NK cell differentiation occurs in the BM, but shortly thereafter, progenitors migrate to SLTs, where they become stage IV NK cells ($CD56^{bright}$ cells). Through a process not yet defined, stage IV NK cells are then exported from SLTs into the PB, where they terminally differentiate into stage V ($CD56^{dim}$) NK cells. Stage III NK cells represent a small progenitor population that makes up about 0.1% to 0.5% of the mononuclear cells in SLTs. Recent studies show that some stage III cells have the unique ability to produce IL-22 and interact with lymph node stroma.[18] These cells have been given many names, including NK22 cells, lymphoid tissue inducer-like cells, and innate lymphoid cells. IL-22 production by these cells occurs in response to inflammatory cytokines, such as IL-1 and IL-23 and bacterial products. IL-22 acts on epithelial cells, causing them to proliferate and elaborate antibacterial proteins, thereby supporting their role in mucosal immunity. These IL-22–producing NK cells also may play a critical role in lymph node repair after viral infection or chemotherapy-induced injury. They also express high amounts of OX40 ligand important in T-cell memory responses. At present, it is not clear whether they are truly NK progenitors or a separate lineage of terminally differentiated innate lymphoid cells. Either way, discovery of these cells has advanced our understanding of SLT biology, and these cells hold promise for improving SLT repair and immune function after allogeneic HCT.

CLINICAL APPLICATIONS OF NATURAL KILLER CELLS

Determination of Donor Natural Killer Cell Alloreactivity

It is widely accepted that the ability of NK cells to contribute to protection from relapse and infection requires that they be functionally competent and present in sufficient numbers. As already described, NK cells are alloreactive against targets that lack self-HLA ligands for the inhibitory receptors that contributed to their education or licensing. Fortunately, the NK cell repertoire is diverse, allowing NK cell education to occur through multiple receptors. Several models have been developed to predict NK cell alloreactivity. KIR–ligand mismatch or incompatibility, as defined by the Perugia group, predicts that donor-derived NK cells will be alloreactive in the GvH direction when recipients lack C2, C1, or Bw4 alleles that are present in the donor. To predict alloreactivity, the receptor–ligand model also requires knowledge of the expression of a particular inhibitory KIR in the donor. Alternatively, in the KIR–ligand absence model, alloreactive potential is based entirely on the number of KIR ligands a recipient lacks. Because KIR genes have multiple alleles with variable levels of expression and functional activity, alloreactivity may be best determined by evaluating the donor KIR genotype with functional assessments of their KIR phenotype.

The Role of Natural Killer Cells in Hematopoietic Cell Transplantation

After HCT, NK cells are the first lymphocyte population to reconstitute. Engrafted alloreactive NK cells may mediate (1) decreased rates of GVHD by targeting of host APC, (2) improved engraftment by secretion of cytokines and elimination of host immune barriers, (3) decreased rates of relapse, and (4) decreased infectious complications. A seminal report published by the Perugia group demonstrated a beneficial effect of alloreactive NK cells and showed that KIR-ligand mismatched NK cells play a key role in achieving durable remission after T-cell deplete haploidentical transplantation for AML but not ALL. KIR–ligand mismatched donors were associated with improved engraftment and decreased relapse and decreased GVHD.[19] However, in a long-term follow-up of 112 patients, only decreased relapse in patients transplanted while in complete remission and improved disease-free survival were maintained. Subsequent analyses of the role of KIR–ligand mismatching and KIR–ligand absence in different settings have produced mixed results. In umbilical cord blood (UCB) transplantation, the effect of KIR–ligand mismatching on outcomes appears to depend on either the intensity of the preparative regimen or the drugs used (i.e., ATG or not).[20,21] In a 2009 study of 169 children treated with autologous HCT for neuroblastoma, KIR

ligand absence was strongly associated with improved survival and decreased risk of disease progression.[22] Inconsistent effects of KIR–ligand mismatch and KIR–ligand absence strategies are likely attributable to differences in the stem cell source, conditioning, degree of T-cell depletion, and post-HCT immunosuppression used, all of which can affect NK cell development, education, and function. Despite this confusion, NK cell effects continue to emerge, implicating them as key effectors reconstituting after transplant capable of protecting against relapse in myeloid malignancies. Similar promise has been demonstrated in pediatric, but not adult, ALL, suggesting that unique interactions between NK cells and targets might account for these differences.

Natural Killer Cell Function After Hematopoietic Cell Transplantation

Despite their high numbers early after transplantation, it is unknown whether these NK cells were fully functional. This question has been explored by several investigators.[23,24] Recently, Foley et al[25] studied simultaneous NK cell functions. They demonstrated that degranulation stimulated by class I negative targets recovered early after transplant, suggesting that NK cells could be educated through either NKG2A or KIR. NK cells from double umbilical cord grafts exhibited CD107a hyperfunction compared with adult unrelated donors (URDs), which may explain the enhanced relapse protection seen in this setting. In marked contrast, IFN-γ production was severely diminished for at least 6 months after HCT, especially in settings of T cell–depleted grafts (even without posttransplant immune suppression) or grafts containing naïve T cells (UCB), suggesting that NK cells require T cells for optimal education. This defect could be rapidly reversed by short-term exposure to IL-15. In addition, and in contrast to CD107a degranulation, IFN-γ production could only be educated through self-KIR (NK cells expressing KIR that encounter their cognate ligand [MHC class I] in the recipient), suggesting a hierarchy of thresholds for different NK effector functions. Last, different conditioning regimens may have varied effects on the tempo of NK and T-cell reconstitution after transplantation and may therefore affect function and impact on clinical outcomes.

Donor Selection Based on Killer Immunoglobulin-like Receptor Genotype

Another approach to capitalize on the beneficial effects of NK cells after HCT is to consider the full KIR genotype of the donors. In a study of 448 patients undergoing myeloablative HLA matched or mismatched URD HCT for AML, the 3-year overall survival was significantly higher after transplantation from a KIR B/x genotype donor (containing at least one B haplotype), irrespective of recipient KIR genotype, with a 30% improvement in relative risk of relapse-free survival.[26] A subsequent analysis of 1409 URD transplant recipients confirmed these findings and refined the beneficial effect of KIR B genes to AML patients. Similar effects were not seen in ALL. Additionally, this later study showed that the most benefit from donor KIR B genotype was localized to genes present in the centromeric part of the KIR locus. The greatest protection from relapse and best disease-free survival, in both HLA-matched and -mismatched transplants, was associated with donors homozygous for this region. Donors could be stratified by KIR into those with best (Cen-B homozygous present in 11% of the population), better (≥2 B defining domains as seen in 20% of the population), or neutral donor KIR genotypes. A publically available calculator to determine this stratification is available online (http://www.ebi.ac.uk/ipd/kir/donor_b_content.html). KIR genotyping as few as three of the best HLA-matched donor candidates should substantially increase the frequency of URD transplants from donors with favorable KIR gene content (from 31% to 79%) in AML.[27] A prospective trial designed to select donors for relapse protection is underway. The benefit of donor KIR B/x has been verified in other studies. The B-haplotype KIR genes 2DL5A, 2DS1, and 3DS1 were associated with an AML-specific fourfold reduction in relapse in a study of 246 T-cell depleted HLA-matched sibling transplants, and KIR B haplotypes were associated with improved survival and reduced TRM in association with less CMV reactivation in otherwise similar patients. A 2010 study of 86 nonmyeloablative, T-cell replete HLA haploidentical HSCTs found a protective effect on relapse, TRM, DFS, and OS when there were mismatches of inhibitory KIR genes between the donor and recipient or when KIR A/A recipients received grafts from donors with at least one KIR B haplotype.[9] In addition to HLA matching, donor selection for KIR genes is a promising strategy to improve outcome after HCT. As recently shown, the benefits of NK cells can be realized in the HLA-matched setting and even in the autologous setting.[10]

Manipulation of Natural Killer Cell Alloreactivity

Another attractive strategy to enhance NK cell alloreactivity is to manipulate the KIR repertoire itself. Therefore, it is of great interest to understand how individual NK cells acquire KIR as they differentiate from stem cells. In general, the stochastic expression of KIR follows the product rule, meaning that the probability of the coexpression of two or more different KIRs equals the product of the individual expression frequencies for those KIRs. The expression frequencies of individual KIRs are independent of MHC class I and are instead established and maintained by a dynamic, yet ill-defined, transcriptional program. Although KIR promoter methylation clearly controls gene expression, other mechanisms are also involved. The Anderson laboratory has identified a number of noncoding RNAs subsequently found to be important in KIR transcriptional regulation.[28] Understanding the molecular mechanisms that underlie KIR expression may help guide the design of novel NK cell strategies with specific KIR repertoires tailored to enhance NK cell efficacy.

Control of Viral Infection

Current studies also support the concept that NK cells play an important role in controlling infections, including those which result in significant morbidity after allogeneic HCT. Interestingly, many observations concerning the development of self-tolerance by NK cells in the context of tumor recognition do not seem to apply in the setting of viral infection. This is likely attributable to a decrease in MHC and an increase in stress-induced ligands on the infected cells, which are recognized by NK cell–activating receptors.[29,30] Some NK cell–activating receptors (NKp44 and NKp46) bind directly to viral epitopes (hemagglutinin), suggesting that they are involved in the control of infections. Likewise, the KIR genotype of donor NK cells appears to also play an important role in control of infections. For example, in a study of donor and recipient CMV seropositive sibling transplants, a 65% reduction in CMV reactivation was observed with donors who had more than one activating KIR gene.[31] Other receptors are also involved in recognition of infectious organisms, including NKG2C. In the solid organ transplant setting, CMV reactivation resulted in an increase in a population of $NKG2C^+$ NK cells.[32] This was not observed in CMV seronegative recipients. The $NKG2C^+$ population was also found to expand in victims of a recent hantavirus outbreak in Sweden, suggesting that specific NK cell subsets are involved in the response to viral infection. Another study of the effect of donor KIR genotype on infections after URD HCT suggests a protective benefit against bacterial infections with donors with the more activating B/x genotype. Interest is growing rapidly in the investigation of the role of NK cells on infection complications.

Adoptive Transfer of Natural Killer Cells

Although methods to exploit the beneficial effects of NK cells engrafting after allo-HCT are increasing, it should be recognized that NK

cells are also well suited for adoptive cellular therapies. Many groups tested methods to induce autologous NK cell activity, such as treatment with prolonged, low-dose subcutaneously IL-2, higher dose IV IL-2, and infusions of ex vivo IL-2 activated NK cells. Although these approaches induced in vivo NK cell expansion and function, they were shown by several investigational teams to have only limited clinical efficacy. Therefore, the Minnesota Group pioneered the use of haploidentical NK cell infusions. This approach was based on the likelihood that haploidentical NK cells, educated in the donor, would be mediate stronger GVL reactions because they are not exposed to immunosuppressive mechanisms seen in cancer patients. It was further hypothesized that this would result in a higher frequency of alloreactive NK cells (NK cells with inhibitory receptors functionally educated through a different inhibitory receptor that will not be inhibited by class I expressed by the tumor). The safety and success of NK cell infusions was established in a trial using haplotype mismatched, related-donor NK cell products followed by subcutaneous IL-2 to induce in vivo NK survival and expansion.[33] Successful expansion was achieved only after a lymphodepleting regimen of high-dose cyclophosphamide and fludarabine. Interestingly, complete remissions in AML correlated with in vivo NK expansion and higher proportions of circulating (and functional) NK cells. The importance of the high-dose chemotherapy regimen delivered before NK cell transfer cannot be overstated. Chemotherapy not only creates space for the NK cells to expand but also results in a surge of endogenous IL-15 and IL-7 and transiently prevents recipient T cells from rejecting the allogeneic NK cells. Importantly, the NK cells that expand in vivo in this platform exhibit hyperfunction, either because of the cytokine milieu induced by the lymphodepleting therapy or by the exogenously administered IL-2. This platform allows in vivo expanded NK cells to partially overcome the rules of NK cell education and tolerance, potentially obviating the need to select specific alloreactive NK cell donors. This assumption requires formal clinical testing. Other modifications are currently being explored to improve in vivo expansion or persistence, including the elimination of regulatory T cells that may impair NK function. Adoptive transfer of haploidentical NK cells has been tested in other settings. In a pediatric cohort, recovery of functional donor-derived $CD56^+/CD16^+$ NK cells that lysed K562 targets mediated strong ADCC activity against neuroblastoma and leukemic blasts by ay +14 after the infusion. The use of NK cell–based therapies to target minimal residual disease is being tested. This preemptive approach is being tested by use of NK cell donor lymphocyte infusions after haploidentical HCT to in adults with AML.[34] A recently published study in pediatric patients used NK cells as consolidation therapy to maintain remissions in a nontransplant setting. This platform is being adapted for testing in elderly AML patients. Additional studies to explore applications in multiple myeloma, lymphoma, and solid tumors are being developed.

FUTURE DIRECTIONS

Several promising strategies to exploit NK cell alloreactivity to treat cancer are in development. These include various approaches to develop in vivo or ex vivo expanded products, manipulations of the host immune system, and strategies to modify the tumor targets to enhance their sensitivity to NK cell–mediated killing (Fig. 102-2). Unlike T cells, haplotype mismatched NK cells can be given without risk of graft-versus-host disease (GVHD). However, adoptive transfer is limited by the cell dose attained from leukopheresis and the current requirement for high-dose lymphodepleting chemotherapy. In vivo expansion, although detectable, is minimal, transient, and appears to require the use of exogenous cytokines such as IL-2, which is associated with significant side effects. The use of IL-15, which is the true homeostatic factor for NK cells, is now being tested in patients receiving adoptively transferred NK cells to treat their acute myeloid leukemia. A major advantage to IL-15 is that unlike IL-2, it does not stimulate regulatory T cells. If it proves safe, the use of IL-15 to stimulate NK cells may overcome the need for high-dose lymphodepleting chemotherapy. Platforms that use IL-2 will likely need to be combined with strategies to deplete host regulatory T cells. Various methods to enrich the NK cell fraction in haploidentical apheresis products are being tested, including depletion of T (CD3) and B (CD19) cells or positive selection for $CD56^+$ NK cells. Several investigators are also exploring ex vivo NK expansion using Epstein-Barr virus transformed or modified K562 feeder cells to increase the infused NK cell dose, potentially circumventing the need for in vivo expansion. The use of "off-the-shelf" NK cell lines, such as NK92 and KHYG-1, may provide a large supply of highly cytotoxic NK cells that could be used for repeated infusions. Other approaches using NK cell products derived from UCB stem cells, embryonic stem cells, or induced pluripotent stem cell sources are also being developed. UCB stem cell derived NK cells that produce IL-22 may enhance tissue integrity and improve immune reconstitution after HCT. Alternative forms of activation, such as combining NK cells with either Toll-like receptor agonists or DC vaccines, are also being explored. Other strategies include sensitizing the target cells using chemotherapy (bortezomib or histone deacetylase inhibitors) or, in the case of solid tumors, irradiation. Last, if cytokines such as IL-15 can safely and efficiently expand autologous NK cells in vivo, it may be possible to mimic an allogeneic approach by using antibodies that block inhibitory receptors. Anti-KIR and anti-NKG2A reagents are currently under development and may functionally convert tolerant autologous NK cells into alloreactive antitumor effectors.[35,36]

FUTURE DIRECTIONS

The therapeutic use of NK cells is a promising strategy in both transplant and nontransplant settings. NK cells have the potential to induce graft-versus-tumor effects without the devastating side effects of GVHD. To date, the majority of evidence supporting NK cells as antileukemia effectors has emerged from the allo-HCT literature. However, the complexities of allo-HCT, including variations in preparative regimens, stem cell sources, graft products, and posttransplant immune suppression, as well as disease specific differences, all contribute to the challenge of understanding mechanistic actions of these cells and to designing effective therapies that exploit NK cell alloreactivity. Investigators developing adoptive NK cell strategies are working to establish proof of concept and to develop exportable techniques. Platforms that support robust in vivo or ex vivo NK cell expansion and education, selecting NK donors based on their NK cell receptor genes, manipulation of tumor NK receptor ligand expression, and coordinating interactions with other immune cells are underway at many institutions. Ultimately, combination therapy using several strategies will likely prove most successful. In particular, agents including IL-15 and antibodies to block inhibitory receptors hold great promise.

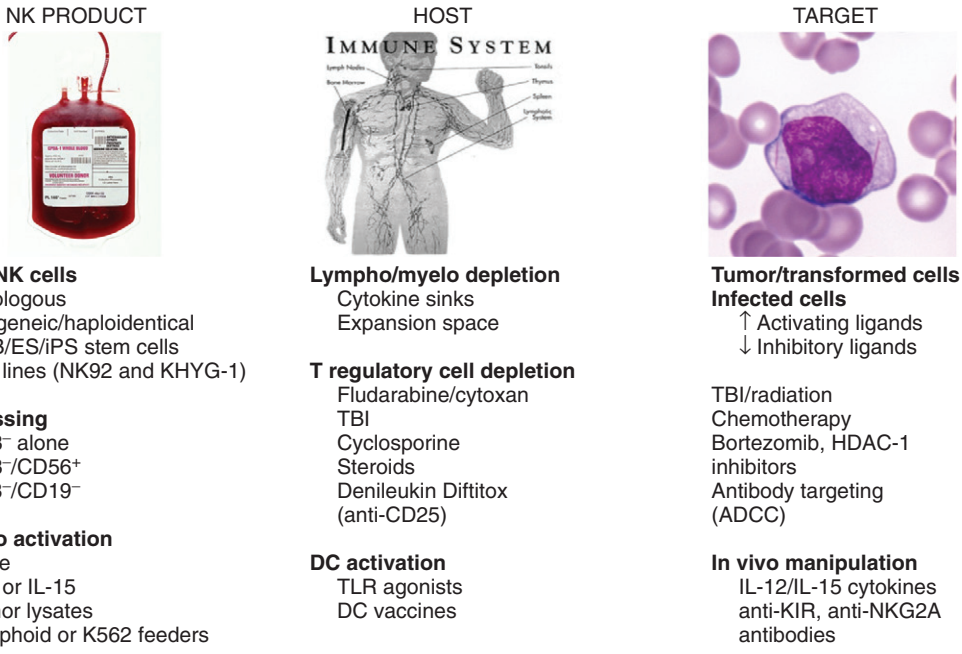

Figure 102-2 MANIPULATIONS TO INCREASE THE EFFECTIVENESS OF ADOPTIVE NATURAL KILLER (NK) CELL THERAPIES. Current approaches to improve the effectiveness of adoptive transfer of NK cells involve a balance between factors from the NK cell product, the host, and the tumor target. The NK cell product can be derived from adult blood and can be autologous (although there is greater concern for "self" major histocompatibility complex inhibition through inhibitory receptors), allogeneic, derived from primitive progenitors, or from NK cell lines; all of which may be more amenable to gene therapy. The optimal product may be the one that gives rise to longer in vivo persistence and survival, which needs formal testing. Use of donor NK cells infused across allogeneic barriers is complicated and clinical trials have been published using each of these manipulations. At a minimum, a T cell–depleted product is needed to prevent graft-versus-host disease. Contaminating B cells have also been shown to contribute to complications such as Epstein-Barr virus–induced lymphoproliferative disease and autoimmune hemolytic anemia as part of a passenger lymphocyte syndrome. It is still unclear whether NK cell products should be administered without activation (fresh or frozen), with interleukin-2 (IL-2) or IL-15 (early in clinical development), or using activation through other mechanisms (tumor cell lysates). Several investigators are exploring ex vivo expansion, a process that requires lymphoblastoid cell line or membrane-bound IL-15 and 41BB-ligand transduced K562 feeders. The success of adoptive transfer is also dependent on host factors that determine whether the recipient is permissive to adoptive transfer. NK cell proliferation depends on lymphodepletion allowing for transient removal of cytokines sinks to free up cytokines such as endogenous IL-15 as well as added myelodepletion that provides space for adoptively transferred cells. Immune barriers to adoptive transfer include an increase in regulatory T cells, especially when IL-2 is administered to the patient, and methods to blunt this inhibitory response may be effective if they do not dampen NK cell function. As NK cells and dendritic cells (DCs) coactivate each other, use of DC vaccines or Toll-like receptor 7 (TLR-7) or TLR-9 agonists that work through DC may be synergistic. Last, a number of manipulations involve the target itself to enhance sensitivity to NK cell adoptive transfer. These manipulations are intended to promote interactions between NK cells and their targets based on known biology to enhance activation interactions, decrease inhibition, or prolong NK cell survival. It is anticipated that a combination of these variables will ultimately be needed for clinical efficacy, and these strategies may need to be tailored to different tumor types. *ADCC,* Antibody-dependent cell-mediated cytotoxicity; *ES,* embryonic stem cells; *HDAC-1,* histone deacetylase 1, *iPS,* induced pluripotent stem cells; *TBI,* total-body irradiation; *UCB,* umbilical cord blood.

CHAPTER 103

DENDRITIC CELL THERAPIES

Karolina Palucka and Jacques Banchereau

The immune system has the potential to eliminate neoplastic cells. Perhaps the most compelling evidence of tumor immunosurveillance in humans is provided by paraneoplastic diseases that associate neurologic disorders to an antitumor response. Onconeural antigens, which are normally expressed on neurons, can also be expressed in breast cancer cells. Some patients develop a strong antigen-specific $CD8^+$ T-cell response that controls tumor expansion but concomitantly results in autoimmune cerebellar degeneration, causing a severe neurologic disease.

The adoptive transfer of cancer antigen-specific effector T cells in patients can result in rejection of established tumors, thereby illustrating the potential of tumor immunotherapy. Ideally, one would like to directly induce efficient tumor-specific T cells through vaccination, including effector T cells able to reject tumors and memory T cells able to prevent tumor relapse. Therapeutic vaccines have two objectives: priming antigen-specific T cells and reprogramming memory T cells, that is, a transformation from one type of immunity to another (e.g., regulatory to cytotoxic). Recent successful phase III clinical trials showing improved survival in patients receiving cancer vaccines have revived this field. Dendritic cells (DCs) are essential in generation of immune responses and as such represent both targets and vectors for vaccination. DCs are a rare cell type that has been discovered by Ralph Steinman in 1973. After 4 decades of research, it is now clear that DCs are at the center of the immune system through their ability to control both tolerance and immunity.

Indeed, murine models demonstrate that the generation of protective anti-tumor immunity depends on the presentation of tumor antigens by DCs.[1,2] There, DCs can capture tumor antigens released from tumor cells, either alive or dying and cross-present these antigens to T cells in tumor draining lymph nodes. This antigen presentation results in the generation of tumor-specific effector T cells that contribute to tumor rejection.[1,2] Thus, DCs represent important targets for therapeutic interventions in cancer.

BASICS OF DENDRITIC CELL BIOLOGY

Dendritic cells are bone marrow–derived cells that seed all tissues (reviewed by Steinman[3]). They are poised to sample the environment and transmit the gathered information to cells of the adaptive immune system (i.e., T cells and B cells).[3,4] In peripheral tissues, DCs capture Ags in the tissues through several complementary mechanisms. DCs launch the immune response by presenting the captured Ag in the form of peptide–major histocompatibility complex (MHC) complexes to naive (i.e., antigen–inexperienced) T cells in lymphoid tissues. Upon interaction with DCs, naive $CD4^+$ and $CD8^+$T cells differentiate into antigen-specific memory T cells with different functions. $CD4^+$ T cells can become Th1, Th2, Th17, or T follicular helper cells (Tfh) that help B cells differentiate into antibody-secreting cells (Tfh) as well as regulatory T cells (Tregs) that downregulate the functions of other lymphocytes. Naive $CD8^+$ T cells can give rise to cytotoxic effector lymphocytes (CTLs).

In the steady state, nonactivated (immature) DCs present self-antigens to T cells, thereby leading to tolerance through either T-cell deletion or differentiation of regulatory/suppressor T cells. These immature DCs have special characteristics, including (1) the ability to efficiently capture antigens, (2) accumulation of MHC class II molecules in the late endosome–lysosomal compartment, (3) low levels of costimulatory molecules expression, (4) a unique set of chemokine receptors that allow their migration to lymphoid tissues (e.g., CCR7), and (5) a limited capacity to secrete cytokines.[5] In contrast, mature antigen-loaded DCs can launch the differentiation of antigen-specific T cells into effector cells with unique functions and cytokine profiles (Fig. 103-1). Indeed, immature DCs promptly respond to environmental signals and differentiate into mature DCs. DC maturation is associated with (1) downregulation of antigen-capture activity; (2) increased expression of surface MHC class II molecules and costimulatory molecules; (3) the ability to secrete cytokines[5]; and (4) the acquisition of CCR7, which allows migration of the DC into the draining lymph node.[5] However, DC maturation does not result in a unique phenotype. Rather, in response to different signals that are provided by different microbes either directly or through the surrounding cells, DCs acquire distinct phenotypes that eventually contribute to diverse immune responses. In addition to cytokines or direct microbial signals, the ligation of CD40 represents an essential signal for the differentiation into fully mature DCs able to launch adaptive T-cell immunity.[6]

DENDRITIC CELL SUBSETS

The type of T-cell response (e.g., helper $CD4^+$ T cell or cytotoxic $CD8^+$ T cell) is at least in part linked with the subset of DCs that presents the antigen to T cells. Humans display two major DC subsets: myeloid DCs (mDCs, also called conventional or classical DCs), and plasmacytoid DCs (pDCs). Blood DC subsets can be distinguished by the differential expression of three surface molecules: CD303 (BDCA-2), CD1c (BDCA-1), and CD141 (BDCA3). $CD303^+$ pDCs represent a front line of antiviral immunity through their ability to secrete large amounts of type I interferon (IFN) in response to virus encounter.[7] Their presynthesized stores of MHC class I may permit a rapid initial $CD8^+$ T-cell response to viral infections. pDCs derived type I IFN may promote the immunogenic maturation of other DC populations, therefore helping in the activation of novel T-cell clones. In their resting state, pDCs are considered as playing an important role in tolerance, including oral tolerance.

Two subsets of blood mDCs can be distinguished by reciprocal expression of CD1c and CD141. Human $CD141^+$ DCs share with mouse $CD8^+$ DCs the high capacity to capture exogenous antigens for presentation on human leukocyte antigen (HLA) class I molecules ("cross-presentation"). $CD141^+$ DCs express XCR1, the receptor for the chemokine XCL1 that is produced by natural killer (NK) cells and activated $CD8^+$ T cells. Thus, mouse $CD8^+$ DCs and human $CD141^+$ DCs are geared up for generation of $CD8^+$ T-cell immunity. In mice, gene ablation studies have shown that the $CD8^+$ subset plays an important role in cross-presentation.[8] However, other human DCs such as epidermal Langerhans cells (LCs)[9] also cross-present antigens. Whether $CD141^+$ blood mDCs are related to DCs subsets in peripheral tissues remains to be determined.

The human skin hosts two main mDC subsets: epidermal LCs and dermal interstitial DCs (dermal DCs) (Fig. 103-2). The dermal

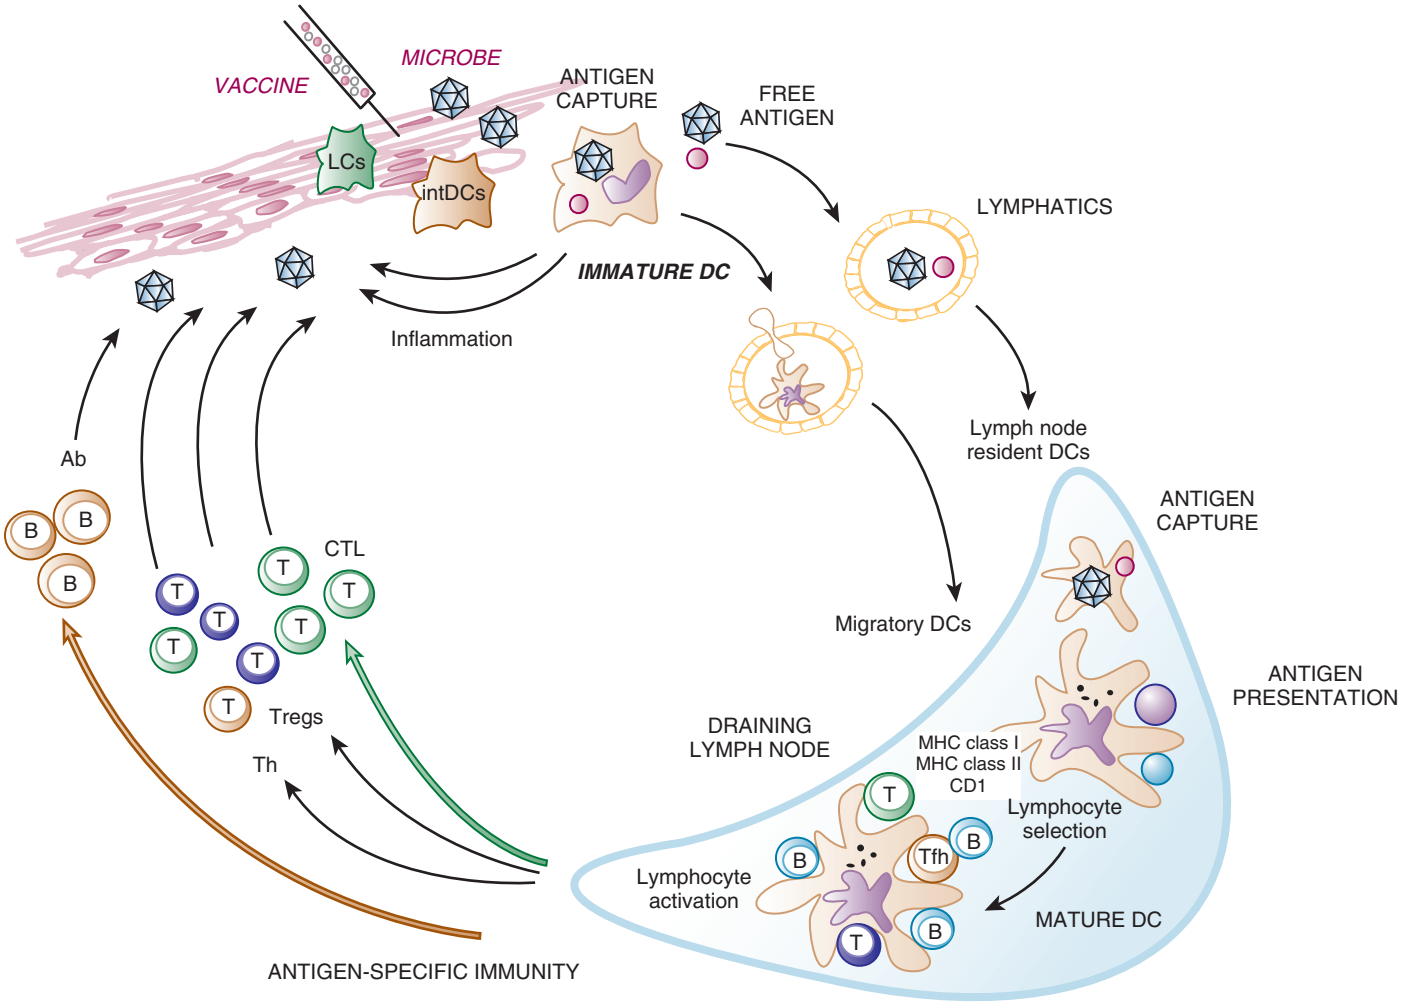

Figure 103-1 LAUNCHING OF THE IMMUNE RESPONSE. Antigen(s) can reach lymph nodes via two pathways. One pathway is via lymphatics, where the antigen is captured by lymph node resident dendritic cells (DCs). The other pathway is mediated by tissue resident DCs. There, immature DCs capture antigens, and DC activation triggers their migration toward secondary lymphoid organs and simultaneous maturation. DCs display antigens in the context of classical major histocompatibility complex (MHC) class I and class II or nonclassical CD1 molecules, which allow selection of rare antigen-specific T lymphocytes. Activated T cells drive DCs toward their terminal maturation, which induces further expansion and differentiation of lymphocytes into effector cells. If DCs do not receive maturation signals, they will remain immature, and antigen presentation will lead to immune regulation, suppression, or both. *CTL,* Cytotoxic effector lymphocyte; *intDC,* interstitial; *Treg,* T regulatory cell.

DCs can be further subdivided into $CD1a^+$ DCs and $CD14^+$ DCs. The authors' studies concluded that human $CD14^+$ DCs can directly help activated B cells as well as induce naive T cells to differentiate into cells with properties of T follicular helper cells (Tfh).[9] They may thus be specialized for the development of humoral responses.[9] On the contrary, LCs are more efficient in cross-presenting peptides from protein antigens to $CD8^+$ T cells and priming $CD8^+$ T cells into potent CTLs.

The DC subsets that sit in tissues under the steady state depend on FLT3 and MCSF-R. However, inflammatory processes such as those initiated by microbial invasion substantially alter the DC compartments. The origin of DCs that are recruited to inflammation sites is still under investigation, but it is clear that monocytes give rise to inflammatory DCs in vivo. Human studies depend on the in vitro exposure of monocytes to different cytokine combinations based on granulocyte macrophage colony-stimulating factor (GM-CSF). GM-CSF can be used together with interleukin-4 (IL-4), IFN-αβ, tumor necrosis factor (TNF), or IL-15 to yield DCs that can activate T cells. The cytokine combination is critical because it results in DCs with different phenotypes and functions. Several of these variants have been administered as vaccines to cancer patients. Another repertoire of tolerogenic DCs can be generated by culturing monocytes with IL-10 or with vitamin A or vitamin D3. Thus, we still need to establish how these distinct DC subsets are related, how they contribute to disease pathogenesis, and how they can be used to design efficient vaccines.

CANCER IMMUNOTHERAPY VIA DENDRITIC CELLS

Immunotherapy is moving to the forefront of cancer therapy owing to recent progresses in the field. For example, an antibody that blocks the function of CTLA-4, a molecule providing negative regulatory feedback in T-cell activation, was approved in 2011 by the U.S. Food and Drug Administration for the treatment of melanoma.[10]

The molecular identification of human cancer antigens has allowed the development of Ag-specific immunotherapy based on different approaches. In one approach, adoptive T-cell therapy (reviewed in[11,12]), autologous antigen-specific T cells are expanded ex vivo and reinfused to patients. The genetic engineering of cancer Ag-specific effector T cells has permitted the generation of promising early clinical data that confirm the therapeutic potential of T cells in cancer. Another approach to Ag-specific immunotherapy is active immunotherapy through immunization (vaccination, i.e., provision

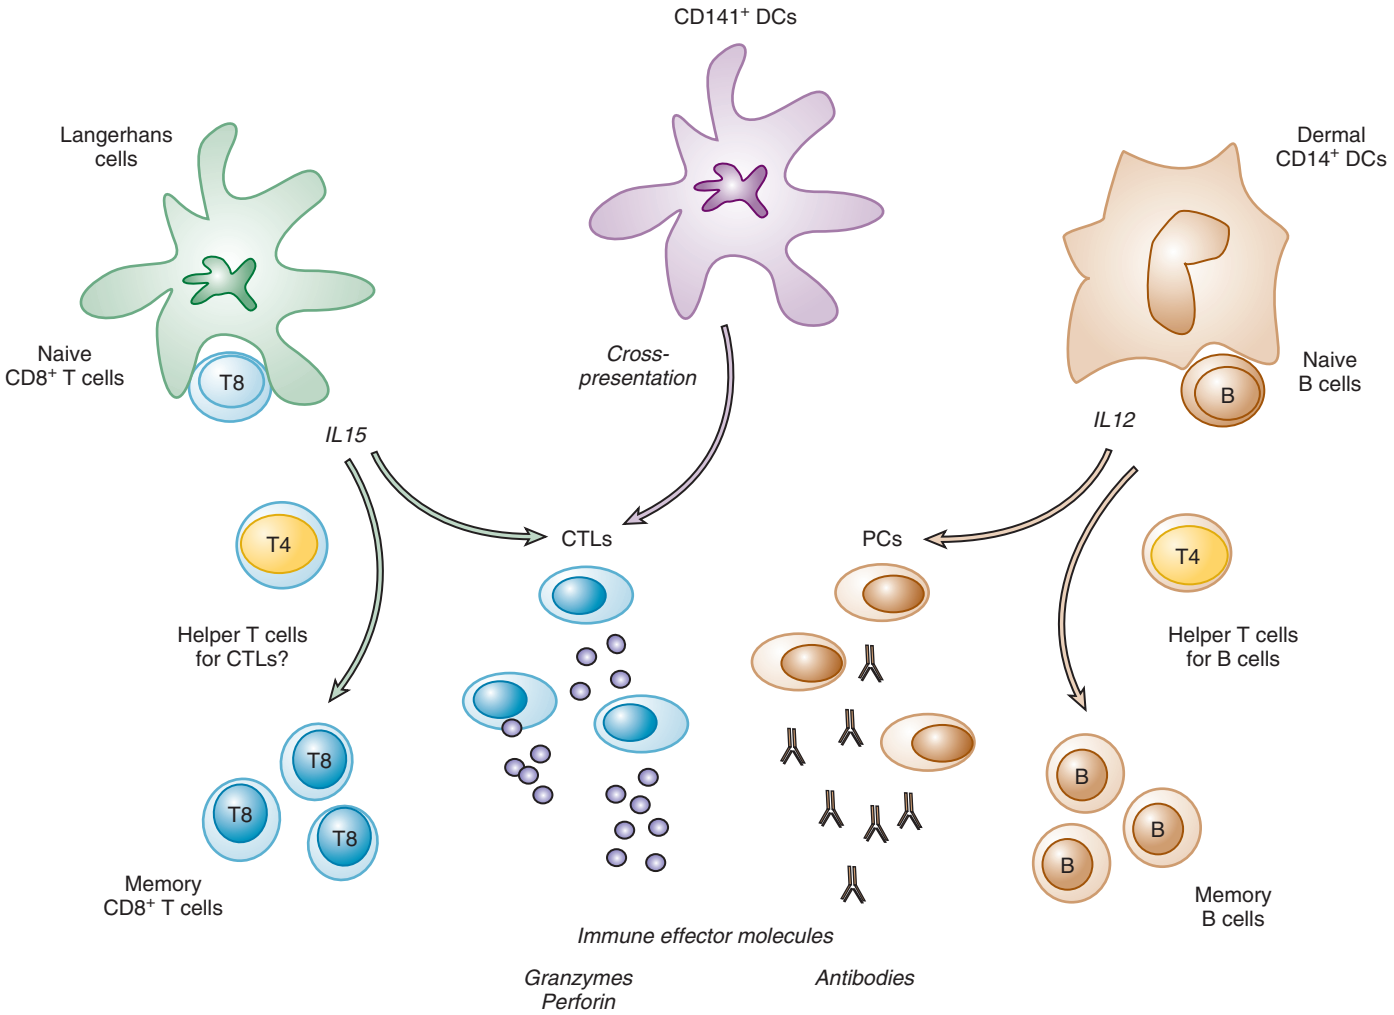

Figure 103-2 DENDRITIC CELL (DC) SUBSETS. The humoral and cellular arms of adaptive immunity are regulated by different human myeloid DC (mDC) subsets. Humoral immunity is preferentially regulated by $CD14^+$ dermal cells (DCs) by means of interleukin-12 (IL-12), which acts directly on B cells and promotes the development of T follicular helper cells (Tfhs). Cellular immunity is preferentially regulated by Langerhans cells (LCs), possibly through IL-15 and a dedicated subset of $CD4^+$ T cells specialized to help $CD8^+$ T cells (cytotoxic effector lymphocyte [CTL] Th cells). Given their capacity to cross-present antigens to $CD8^+$ T cells, $CD141^+$ DCs are likely to be involved in the development of cytotoxic T-lymphocyte responses. $CD141^+$ DCs might also be involved in the development of humoral responses through IL-12 secretion. This hypothesis is supported by mouse in vivo antigen-targeting studies showing that $CD8^+$ DCs, the mouse counterpart of human $CD141^+$ DCs, can induce both cytotoxic T-lymphocyte and humoral responses, although the mechanisms may be different. It will be important to determine whether and how $CD141^+$ DCs are related to LCs and to dermal DCs, and how these DC subsets shape adaptive immunity. *PC,* Plasma cells.

of an antigen together with an adjuvant to elicit an immune response of therapeutic value). Because of their molecular and functional characteristics, DCs are considered "nature's adjuvants." Furthermore, it is now well accepted that vaccine adjuvants (e.g., alum) act via activation of DCs. The progress in our understanding of DC biology will lead to development of next-generation potent cancer vaccines. Current studies aim at generating therapeutic cancer vaccines that are designed to elicit potent $CD8^+$ T-cell immunity able to eradicate tumor cells.

Vaccination via Dendritic Cells

Ex Vivo–Generated Dendritic Cell Vaccines

Dendritic cells generated ex vivo by culturing hematopoietic progenitor cells or monocytes with cytokine combinations have been tested as therapeutic vaccines in cancer patients for more than a decade.[13] These studies concluded that DC-based vaccines are safe and can induce the expansion of circulating $CD4^+$ and $CD8^+$ T cells that are specific for tumor antigens (Table 103-1). Objective clinical responses have been observed in some patients. The clinical response take time to build up, but remissions can be very long lasting.

The selection of tumor antigens for loading the DCs represents an important parameter. Candidate tumor antigens include unique (mutated) antigens and shared nonmutated self-antigens. To generate broadly applicable vaccines, nonmutated self-antigens have often been selected. These, however, present potential shortcomings: (1) the repertoire of high avidity clones might be depleted through negative selection and (2) the existing memory T cells often include regulatory T cells.

Mutated antigens might not display these drawbacks. Cancer vaccines designed to elicit strong immune responses against these mutated antigens will require a fully personalized approach. This represented a considerable challenge a few years ago. Fortunately, the fast development of modern sequencing technologies will allow us to determine the complete repertoire of mutated antigens in the patient's primary tumor and metastasis. This transforming technology might therefore allow us to craft therapeutic vaccines perfectly tailored to the patient's tumor.

Table 103-1 Examples of Clinical Trials Testing Vaccination with Ex Vivo Dendritic Cells

Vaccine/Antigen	Indication	Key Contribution	Reference
GM-CSF/IL-4 DCs with or without HLA-A201 restricted peptides or peptides alone	Metastatic prostate cancer	One of the first studies testing DCs immunogenicity	34
GM-CSF/IL-4 DCs Peptides Tumor lysates Autologous tumor eluted peptides	Stage IV melanoma Renal cancer Malignant glioma	Loading DCs with complex antigen preparations Objective clinical responses	35-37
Blood DCs Idiotype	Multiple myeloma	Immunogenicity Tumor regression	38,39
Mature GM-CSF/IL-4 DCs Peptides	Stage IV melanoma	Well-controlled and validated vaccine manufacture process Testing mature DCs Immunogenicity Objective clinical responses	40
$CD34^+$ HPC-derived DCs Peptides	Stage IV melanoma	First studies to test $CD34^+$HPC-dervied DCs Loading vaccines with a mixture of well-defined peptides Durable immune responses in long-term survivors Objective clinical responses	41,42
FLT3 ligand expanded blood DCs Altered peptides	Advanced CEA^+ cancer	Immunogenicity Objective clinical responses	43
Immature GM-CSF/IL-4 DCs	Healthy volunteers	Antigen-specific inhibition of effector T-cell function after injection of immature DCs	44
GM-CSF/IL-4 DCs Tumor lysates	Refractory pediatric solid tumors	Immunogenicity Objective clinical responses	45
Mature cryopreserved GM-CSF/IL-4 DCs	Stage IV melanoma	Immunogenicity	46
DCs loaded with killed allogeneic tumor cells	Stage IV melanoma	Immunogenicity Durable objective clinical responses Long-term survival	47,48
Monocyte-derived DCs Loaded with NK T-cell ligand GalCer	Advanced cancer	Adjuvant effect of NK T-cell activation on $CD8^+$ T-cell immunity	49
Monocyte-derived DCs	Melanoma	In vivo identification of antigen-specific immune response by PET imaging in patients	50
Monocyte-derived DCs	Melanoma	Route of DC administration impacts T-cell activation with intradermal administration showing better responses than intranodal	51
Comparative study $CD34^+$ HPCs derived LCs vs. monocyte DCs	Melanoma	LC-based vaccines stimulated significantly greater tyrosinase-HLA-A*0201 tetramer reactivity than the monocyte DC-based vaccines	52

Targeting Antigen to Dendritic Cells in Vivo

Dendritic cells can be engaged by delivering antigens directly in vivo using chimeric proteins made of anti-DC receptor antibody fused to a selected antigen (DC targeting). Ralph Steinman and his colleagues demonstrated that the specific targeting of antigens to DCs in vivo results in the elicitation of potent antigen-specific $CD4^+$ and $CD8^+$ T-cell immunity.[14] The induction of immunity necessitates that maturation signals are provided.[14] Otherwise this strategy can result in antigen-specific tolerance, a finding of significant value in the context of autoimmunity. The use of vaccines targeting surface molecules expressed on different DC subsets allowed Steinman and Nussenzweig to formally demonstrate that distinct DC subsets elicit distinct immune responses.[15] There, $CD8^+$ DCs that express the whereas cell surface protein CD205 present delivered antigens in the context of both MHC class I and class II, $CD8^-$ DCs, which are positive for the 33D1 antigen, are specialized for presentation on MHC class II.[15] Furthermore, targeting antigen to these distinct receptors on DCs leads to generation of T-cell responses via independent pathways. Thus, DEC-205 expressing DCs generate Th1 response in an IL-12–independent CD70-dependent mechanism, but $33D1^+$ DCs generate Th1 responses through the classic IL-12[16] pathway. DC targeting is not purely confined to the delivery of an antigenic cargo inasmuch as the engagement of some surface molecules such as Dectin-1, DC-SIGN, and CD40 by targeting antibodies provides activation signals as well. It remains important to determine whether the

activation signals might actually polarize the DCs in the desired fashion. Thus, the challenge will be to match the DC surface target and the selected adjuvant with the desired immune outcome, all this in the context of an altered immune system.

IMMUNE AND CLINICAL EFFICACY

Most phase I/II studies have stumbled on two critical issues: (1) how to assess the clinical efficacy of cancer immunotherapy and (2) how to define the correlates (biomarkers) of clinical efficacy. In the early days, the RECIST (response evaluation criteria in solid tumors) criteria that had been designed to assess chemotherapy-based trials were considered critical to assess of clinical efficacy in vaccine and immunomodulation trials.[17] This has recently been challenged because in the early phase of treatment, tumors might increase in size, which might actually reflect the inflammatory process associated with active immune responses and lymphocyte infiltration.

Thus, overall survival might actually be the only objective parameter of clinical efficacy. However, surrogate markers are needed because trials based on overall survival might be exceedingly long. A number of cancer vaccine studies have suggested that the therapeutic vaccination outcome, success or failure, correlates with the vaccine-induced expansion of antigen-specific effector T cells.[18] However the quality, more than the quantity, of the antigen-specific immune response remains one of the key parameters of efficacy.

Indeed, the immunologic goal of vaccination against cancer is to elicit tumor-specific $CD8^+$T cell responses that will be sufficiently robust and long lasting to generate durable tumor regression or eradication (or both) as we have already discussed above. Ideally, vaccine-elicited $CD8^+$ T cells should (1) be of high avidity and able to recognize peptide–MHC class I complexes on tumor cells; (2) express high levels of granzyme and perforin, molecules essential for cytotoxic activity against cancer cells; (3) be able to traffic into the tumor; and (4) overcome regulatory mechanisms present in the tumor.[19] At least four components of the immune response are necessary for that ideal response to happen: (1) the presence of appropriate DCs, (2) the quality of induced $CD4^+$ helper T cells, (3) the elimination or non-activation (or both) of Tregs, and (4) the breakdown of the immunosuppressive tumor microenvironment. Here we will briefly elaborate on the fate of $CD8^+$ T cells in the context of DC vaccination. Naive $CD8^+$ T cells initiate a CTL differentiation program upon encounter with DCs presenting tumor-derived peptides.[20] A complex system of signals drives the subsequent $CD8^+$ T-cell expansion and differentiation, which include costimulatory pathways mediated by co-stimulatory molecules CD80, CD70, and 4-1BB as well as DC-derived cytokines such as IL-12 and IL-15. The quality of $CD8^+$ T cell differentiation is further regulated by $CD4^+$ T cells[21] through (i) help for the differentiation and expansion of tumor antigen-specific CTLs; (ii) induction of long-term memory $CD8^+$ T cells. Unfortunately, $CD4^+$ T cells can also suppress CTL differentiation. Thus, Tregs can inhibit CTLs via the secretion of various cytokines including transforming growth factor-β (TGFβ). They can also compete with $CD8^+$ T cells for IL-2 via constitutive expression of CD25.[22]

Antigen-specific CTLs must also traffic into the tumor bed, an area that is not clearly understood.[19] A dysregulation of chemokine homeostasis might prevent the $CD8^+$T cells from entering the tumor bed. Tumors might also actively repulse $CD8^+$ T cell.[23] Finally, the tumor-infiltrating myeloid-derived suppressor cells and Tregs[24,25] might inhibit effector $CD8^+$ T-cell functions. The negative cues of the tumor environment can be counteracted by a series of therapeutic modalities. Both antibodies that neutralize cytokines, such as IL-10, IL-13, and TGFβ and antibodies such as anti-CTLA-4 and anti-PD-L1, which block the immune-inhibitory signals in lymphocytes, will represent important contributors to cancer vaccines. Likewise, antibodies such as anti-CD137 that further promote costimulation of effector T cells should be tested in conjunction with vaccination. Just as oncologists currently use different combinations of cytostatic drugs and targeted therapies to treat cancer patients, we foresee the development of clinical protocols combining DC vaccines with individualized adjunct therapies.

"ENDOGENOUS" VACCINATION

The classical cancer therapies that are based on chemotherapy might in fact be effective partly through the engagement of the immune system. For example, chemotherapeutic agents such as anthracyclines and oxaliplatin induce cancer cells to undergo apoptosis, which is associated with cell surface exposure of calreticulin. Surface calreticulin might contribute to the capture of apoptotic bodies by DCs and the elicitation of tumor-specific $CD8^+$ T-cell immunity. These T cells might contribute to the elimination of the tumor cells[26] that have not responded to the chemotherapy.

There is now strong evidence that antibody therapy with agents such as anti-CD20 and anti-HER2 involve the adaptive immune system beyond the elicitation of antibody-dependent cytotoxicity (ADCC). Indeed, antibodies against HER2 can enhance cross-presentation of tumor antigens, leading to the break of tolerance against this antigen.[27] Accordingly, patients responding to trastuzumab (Herceptin) show enhanced $CD8^+$ T-cell immunity to HER2.[27]

MODULATING DENDRITIC CELLS IN THE TUMOR ENVIRONMENT

Another approach to immunotherapy via DCs is focused on exploiting DCs in the tumor microenvironment (Fig. 103-3). Indeed, DCs are found in most tumors in humans and mice. DCs can sample tumor antigens through the capture of dying tumor cells and through the nibbling of live tumor cells (reviewed in[28]). Tumors can prevent antigen presentation and the establishment of tumor-specific immunity through a variety of mechanisms. By converting immature DCs into macrophages (i.e., through IL-6, and M-CSF [macrophage colony-stimulating factor]), tumors can prevent the priming of tumor-specific T cells. Alternatively, the tumor glycoproteins carcinoembryonic antigen (CEA) and MUC-1 that are endocytosed by DCs stay confined in the early endosomes, therefore preventing efficient processing and presentation to T cells.

Tumors also interfere with DC maturation. First, they can inhibit DC maturation (i.e., through the secretion of IL-10, leading to Ag-specific anergy). Second, tumor-derived factors can alter mDCs maturation so as to yield cells that indirectly help tumor growth ("protumor" DCs). As an example, we have shown that thymic stromal lymphopoietin (TSLP) that is produced by tumor cells induces DCs to express OX40-L that directs the generation of Th2 cells. These skewed $CD4^+$ T cells accelerate breast tumor development through the secretion of IL-4 or IL-13. These cytokines prevent tumor cell apoptosis and promote the proliferation of cancer cells indirectly by stimulating tumor-associated macrophages to secrete epidermal growth factor (EGF). A similar pathway operates in pancreatic cancer.[29]

Plasmacytoid DCs that are infiltrating breast carcinomas produce little type I IFN upon TLR ligation.[30] These pDCs induce naive $CD4^+$T cells to differentiate into IL-10–producing T cells with suppressive functions. Such inhibition of type I IFN secretion might also impact the generation of effector T cells because DCs require type I IFN signals to cross-present tumor antigens.[1,2] Whether this mechanism explains why pDCs are associated with a poor prognosis[31] remains to be determined.

Finally, DCs can have direct protumor effects. In multiple myeloma, mDCs directly promote the survival and clonogenicity of tumor cells.[32] In ovarian cancer, pDCs contribute to tumor angiogenesis by secreting proangiogenic cytokines.[33] Thus, understanding the functions of DCs in the tumor bed might represent a rich field of investigation. Ultimately, rewiring the "protumor" DCs into "antitumor" DCs might represent a novel approach for cancer immunotherapy.

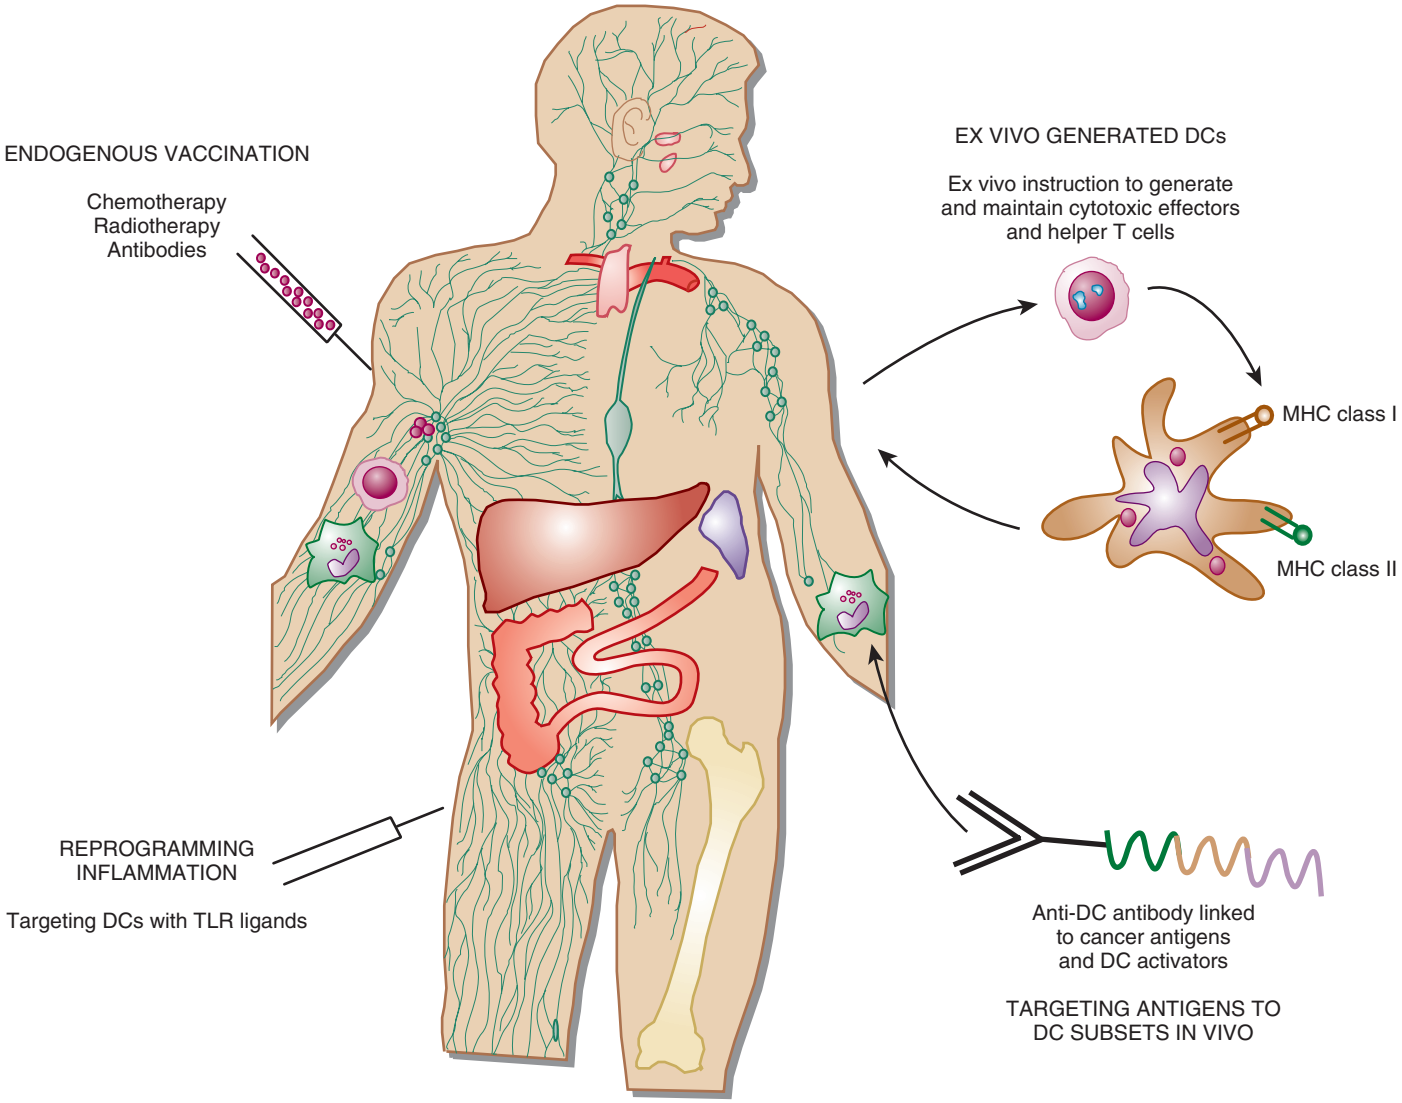

Figure 103-3 DENDRITIC CELLS (DCs) AND CANCER IMMUNOTHERAPY. (1) Random targeting of DCs in "endogenous" vaccination resulting from in vivo antigen release in a process of immunogenic cell death in response to chemotherapy, radiotherapy, or immune modulation approaches targeted at T cells; (2) vaccines based on ex vivo–generated tumor antigen-loaded DCs that are injected back into patients; (3) specific in vivo DC targeting with anti-DC antibodies fused with antigens and with DC activators; and (4) targeting DCs in the tumor environment to reprogram protumor inflammation toward tumor rejection. *MHC,* Major histocompatibility complex; *TLR,* toll-like receptor.

FUTURE DIRECTIONS

Nearly 40 years after their discovery, the importance that DCs has taken in physiology and medicine has been recognized by the award to Ralph Steinman of the Nobel Prize for Medicine and Physiology. Studies performed in the past decade have highlighted the commonalities and uniqueness of the various DC subsets. This new knowledge represents a fertile ground to work on to design better strategies for intervening in numerous clinical situations. The capacity of LCs and $CD14^+$ DCs to preferentially prime cellular immunity and humoral immunity, respectively, has significant implications, most particularly in the context of novel human vaccines. Thus, targeting LCs will be important for the design of vaccines that aim at eliciting strong cellular immunity. Such vaccines might be particularly useful at preventing, and perhaps even treating, chronic diseases, including viral (HIV, hepatitis C virus), bacterial (*Mycobacteria* spp.), and parasitic (malaria) diseases, as well as cancer. The most efficient vaccines might actually be those that will target both $CD14^+$ DCs and LCs, thereby allowing the maximal stimulation of both humoral and cellular immune responses. We foresee that the improved vaccines that target DCs will permit us to treat and prevent many chronic diseases, and likewise, manipulation of DCs will also permit to dampen overly enhanced immune responses as occurs in allergy and autoimmunity, possibly by turning on regulatory mechanisms.

ACKNOWLEDGMENT

We thank all the patients and volunteers who participated in our studies and clinical trials. We thank former and current members of the Institute for their contributions to our progresses. Our studies have been supported by the NIH (P01 CA084514, U19 AIO57234, R01 CA089440, CA078846, and CA140602), the Dana Foundation, the Susan Komen Foundation, the Baylor Health Care System, the Baylor Health Care System Foundation, the ANRS, and the INSERM. KP holds the Michael A. Ramsay Chair for Cancer Immunology Research. Because of space limits, we could cite only a fraction of the vast number of publications.

CHAPTER 104

OVERVIEW OF HEMATOPOIETIC STEM CELL TRANSPLANTATION

Helen E. Heslop

Since the first hematopoietic stem cell transplants (HSCTs) were performed more than 50 years ago, this modality has become a well-established therapeutic option for many hematologic malignancies as well as for bone marrow (BM) failure states, immune deficiencies, and inborn errors of metabolism[1-3] (Table 104-1). The wider application of allogeneic transplantation has been possible because of increased knowledge of the genetic basis of histocompatibility and advances in molecular methodology to more accurately type donors and recipients. In addition, the development of large donor registries and cord blood banks has expanded access to transplant as well as increasing the likelihood that a recipient will find a well-matched donor.[4]

Over the last 20 years, there has also been identification of additional sources of stem cells so that BM, peripheral blood (PB), and umbilical cord blood (UCB) are all widely used in clinical practice to provide long-term hematopoietic reconstitution. The increasing use of reduced-intensity conditioning regimens has made transplant an option for older patients and patients with comorbidities. Finally, there have been improvements in graft-versus-host disease (GVHD) prophylaxis and supportive care during the period of hematopoietic and immune suppression after transplant. Allogeneic HSCT should therefore be considered for patients in whom this procedure is likely to result in superior long-term disease-free survival (DFS) compared with other therapeutic modalities. Potential candidates must also have a suitable source of hematopoietic stem cells (HSCs) available at an appropriate time in the course of the disease.

This chapter provides an overview of HSCT procedures, including conditioning regimens and selection of donor and HSC source and common early and late posttransplant complications. These topics are discussed in depth in Chapters 105 to 110, and the disease specific indications are discussed in the relevant disease chapters (see Table 104-1 for details). Technical aspects of transplant, including HSC harvesting and cell processing, are discussed in Chapters 96 and 98.

ALLOGENEIC TRANSPLANTATION

Allogeneic transplant is a potential treatment for patients with relapsed or high-risk hematologic malignancy as well as for patients with inherited and acquired disorders of the hemopoietic and immune systems. The goal is to replace the recipient's hemopoietic and immune systems with normal HSCs from a closely matched donor whose hematopoietic stem and progenitor cells obtained from donor BM or other sources can home to the recipient's hematopoietic microenvironment and engraft. The major criteria for choosing an allogeneic donor is the degree of histocompatibility between the donor and recipient because the risks of both graft rejection and of GVHD increase with the degree of genetic disparity. The most important determinant of alloreactivity is matching at loci in the major histocompatibility complex (MHC) which includes human leukocyte antigens (HLA), encoded by class I (HLA-A, HLA-B, and HLA-C) and class II (HLA-DR, HLA-DQ, and HLA-DP) genes. HLA molecules were originally defined by serology, but molecular testing is now routine because gene sequencing has revealed multiple alleles for most serologically defined specificities[5] (see Chapter 106). Other determinants include minor histocompatibility antigens, which are naturally processed peptides derived from normal cellular proteins that can stimulate an MHC-restricted response when different polymorphisms are present in donor and recipient. Natural killer (NK) cells may also contribute to alloreactivity, particularly in the setting of haploidentical transplantation. There is also increasing evidence that genetic loci outside of the MHC may influence the risk of transplant complications such as infection or regimen-related mortality and several groups are undertaking genome-wide association assays to define genetic variants that might predict these complications.

The choice of donor for an allogeneic HSCT depends on several factors, including donor choices, the urgency of the transplant, and the patient's disease status. The optimal donor is a matched sibling sharing HLA class I and HLA class II alleles, but because each child inherits one set of paternal and one set of maternal HLA antigens, the likelihood of any sibling matching is only 25%. For patients who lack such donors, other options include a closely matched unrelated or cord donor or a haploidentical family member. Development of high-resolution molecular tissue typing methods and establishment of large donor registries have facilitated transplants from closely HLA-matched unrelated donors. These volunteer donors are healthy individuals between 18 and 60 years of age who fulfill eligibility requirements similar to those applied to blood donors. With increasing registry size, the chance of finding a donor has increased, so that more than 70% of patients can identify an HLA-A, B, C, and DRB1 allele-matched unrelated donor.[6] The likelihood of finding a donor matching at these eight loci (or 10 loci if matching at DQB1 is also included) varies for different ethnic groups and is less for groups with more polymorphism of HLA antigens. The initial results of transplantation from unrelated donors were inferior to those seen after matched sibling transplantation because of increased incidences of graft rejection and of GVHD caused by the greater genetic disparity. Over the past decade, though, results have gradually improved in both single-center and multicenter registry studies, reflecting better donor–recipient matching and advances in GVHD prophylaxis and supportive care.[6] One remaining limitation, though, is the time required to identify and screen an unrelated donor, which can be up to 3 to 6 months. Cord units by contrast can be obtained within 1 week of identifying a suitable matched unit. Haploidentical family donors have the greatest genetic disparity but are usually also rapidly available. Several studies have compared outcomes of cord and haploidentical donor transplants, but they do not show a definitive advantage for either source of HSCs.[7]

AUTOLOGOUS TRANSPLANTATION

Autologous transplant in which the recipient's own HSCs are collected then reinfused after high-dose chemotherapy is used to produce hemopoietic reconstitution after high-dose chemotherapy. This approach allows dose intensification in settings where there is a correlation between dose and tumor response rate and hematopoietic toxicity is a limiting factor for dose intensification. HSCs are harvested and cryopreserved and then reinfused after doses of chemotherapy and radiotherapy that would otherwise be lethal or require a

Table 104-1 Hematologic Disorders Treated by Hematopoietic Stem Cell Transplantation

Hematologic Malignancies	Chapters
Acute lymphoblastic leukemia	64 (pediatric), 65, 105 (adult)

SCID, Severe combined immunodeficiency.

prolonged period of recovery. In general, autologous transplant is well tolerated, and data from the Center for International Bone Marrow Transplant Research (CIBMTR) show that the 100-day mortality rate is less than 5%.[8] The major cause of failure after autologous transplant is relapse of the primary disease. One longer-term concern is that recipients of autologous transplant have an increased risk of secondary therapy-related myeloid leukemia or myelodysplastic syndromes (t-MDS/AML) although this may also reflect effects of previous treatment. Indeed, a study which identified a pattern of altered gene expression in patients who developed t-MDS/AML after transplant for lymphoma found that the genetic programs associated with t-MDS/AML are perturbed pre close up transplant.[9]

The most common indications for autologous transplant are currently, myeloma, non-Hodgkin lymphoma (NHL), and Hodgkin lymphoma, in which it has been shown in randomized trials or concluded in evidence-based reviews that dose intensification and hemopoietic rescue result in improved DFS.[10-12] Patients with newly diagnosed myeloma who are considered potential candidates for autologous transplant ASCT are usually treated with 2 to 4 cycles of therapy that usually includes an immunomodulatory agent and a proteasome inhibitor before proceeding to autograft.[13] High- or intermediate-dose melphalan is the most widely used conditioning regimen with patients who are younger than the age of 65 years and do not have significant comorbidities receiving high-dose regimens (200 mg/m^2); older patients or those with comorbidities receive a reduced dose regimen (usually 140 mg/m^2).[14] The optimal post-autograft therapy is under investigation. A multicenter randomized trial showed no advantage for performing tandem autologous non-myeloablative allogeneic HSCT compared with tandem autologous HSCT for patients with standard-risk multiple myeloma,[15] and current studies are comparing tandem autologous transplants with single transplant followed by maintenance with an immunomodulatory agent or proteasome inhibitor.

Both ASBMT and NCCN guidelines recommend autologous transplantation in patients with relapsed or refractory diffuse large B-cell lymphoma,[10,16] as well as selected patients with follicular lymphoma.[11] Several large studies have also showed benefit from consolidating with an autograft after initial therapy in patients with mantle cell lymphoma.[17,18] A number of different myeloablative conditioning regimens are used in patients with NHL with the most common being BEAM (BCNU, etoposide, cytosine arabinoside, and melphalan), often in combination with rituximab.

SOURCE OF HEMATOPOIETIC STEM CELLS

The major sources of stem cells for transplant are BM, mobilized PB, and cord blood.

Autologous Donors

In autologous transplantation, the source of HSCs is mobilized PB in almost all adults and more than 90% of pediatric patients.[8] Cytokine-mobilized PB stem cells (PBSCs) can be harvested either after treatment with recombinant human granulocyte colony-stimulating factor (GCSF) alone or with GCSF given after chemotherapy. In patients who are heavily pretreated and difficult to mobilize, plerixifor, an antagonist of CXCR4 that interferes with adhesion of hematopoietic progenitors in the microenvironment thereby promoting their circulation in the PB, can be used to increase the mobilization of CD34$^+$ stem cells when given in combination with standard GCSF therapy.

The success of HSC mobilization is related to the amount of previous chemotherapy with some drugs such as alkylating agents having a particularly adverse effect on the success of HSC mobilization. The International Myeloma Working Group has therefore recommended early mobilization of stem cells, preferably within the first 4 cycles of initial therapy.[19]

Allogeneic Donors

Bone marrow was the historic source of HSCs for transplant and remains the most widely used source in children. BM can be harvested from the posterior iliac crests of allogeneic donors in amounts up to 10 to 20 mL per kilogram of recipient weight to obtain sufficient HSCs for engraftment. Cytokine-mobilized allogeneic PBSC harvest has become an alternative to BM as a source of HSCs and is now the most widely used source in adults receiving allogeneic transplants. In both single-center randomized studies and CIBMTR registry studies, use of this source of stem cells from matched sibling donors resulted in more rapid engraftment with no increase in acute GVHD. However, there was a higher incidence of chronic GVHD associated with a lower risk of relapse, which translated to improved DFS in patients transplanted for advanced hematologic malignancies. However, this survival benefit was not seen in patients with early stage disease. A recent large, prospective, randomized trial in recipients of unrelated HSCs who were randomized to receive BM versus PB grafts for hematologic malignancies shows no difference in overall survival at 2 years but a higher incidence of chronic GVHD in the recipients who received PB.[20] Longer follow-up is needed to determine if this more frequent development of chronic GVHD will be associated with higher late mortality.

Umbilical Cord Blood

Another alternative source of stem cells is cord blood. There are several large cord banks where cord blood is collected, cryopreserved, and tested for infectious agents in accordance with standards developed by governmental and specialty oversight organizations.[21] This worldwide network for UCB cell procurement, typing, and storage has collected a large inventory of cords and has facilitated more than 20,000 unrelated donor UCB transplants. A major advantage of cord transplant is the immediate availability of cryopreserved units. Cord transplants have slower engraftment, but they also may also induce less GVHD because of the relative naivety of cord T cells. One limitation is the cell count, which can be limiting for individuals weighing more than 50 kg. However, several studies show that double cord blood transplant, with each unit sharing at least 4/6 HLA antigens with the recipient, can overcome this problem and extend the use of cord transplant to larger adult recipients (see Chapter 108).

CONDITIONING REGIMENS

The conditioning regimen has different roles in autologous and allogeneic transplant. In autologous transplant, the aim of the conditioning regimen is to intensify doses of chemotherapy agents that would be limited by hematopoietic toxicity. In allogeneic transplant, the goal of conditioning is to achieve immunosuppression of the recipient sufficient to prevent rejection of the donor BM cells and to destroy residual malignant cells (see Chapter 105). Historically, patients transplanted for malignancy have received intensive fully ablative regimens in which hematopoietic reconstitution would not occur without HSC support. Conditioning regimens are discussed in more detail in Chapter 105, but the most commonly used allogeneic regimens use total-body irradiation (TBI) and cyclophosphamide or chemotherapy alone with combinations such as busulfan and cyclophosphamide. Biologic agents, such as antithymocyte globulin and monoclonal antibodies, may also be included in some regimens to increase immunosuppression. Reduced-intensity conditioning regimens were developed in the late 1990s and are primarily immunosuppressive, relying on graft-versus-leukemia mechanisms to eradicate malignancy. Reduced-intensity conditioning is often used in older patients or patients with comorbidities in whom the toxicity associated with ablative conditioning would be unacceptable. A variety of regimens based on low-dose TBI or fludarabine have been used.

COMPLICATIONS AFTER STEM CELL TRANSPLANTATION

Patients who receive transplants are at risk of a number of short- and long-term complications and require long-term-follow up. Guidelines for screening and monitoring long-term survivors have been published,[22] and there is increasing interest in research to define the quality of life in long-term transplant survivors. Recipients of both allogeneic and autologous transplant have risks of infection during the period of hematopoietic and immune reconstitution and short- and long-term complications from toxicities from the conditioning regimen. Allograft recipients are also at risk of graft failure and GVHD because of the genetic disparity between donor and recipient.

Acute Graft-Versus-Host Disease

GVHD is the most important cause of mortality, morbidity, and diminished quality of life after allogeneic HCT and results from alloreactivity between donor and recipient. The process is initiated by donor T lymphocytes that recognize antigenic disparities between donor and recipient. In the initial phase, chemotherapy or radiation given as part of the conditioning regimen results in production of inflammatory cytokines secreted by damaged host cells.[23] The release of microbial products that are produced by intestinal flora, as well as the release of cytokines by damaged host tissues, lead to the activation of innate immune cells by pathogen recognition receptors such as Toll-like receptors. After infusion of the HSC product, donor T cells become activated by exposure to host antigens and further activate other immune effectors, resulting in secretion of cytokines and clinical manifestations of GVHD. Chronic GVHD is defined as GVHD occurring after day 100 after transplant, although this definition is somewhat arbitrary. Chronic GVHD often occurs in a patient who has had preceding acute GVHD, although it may arise de novo. It targets the skin, liver, and gastrointestinal tract but may also target other organs and shares features with autoimmune diseases such as scleroderma.

Graft Failure

Graft failure results when recipient immune system cells that survive the conditioning regimen are able to eliminate the incoming donor BM. It is uncommon after fully ablative allogeneic HSCT for hematologic malignancies, but higher incidences are seen after reduced-intensity conditioning and when cord blood is the source of HSCs. Other risk factors include the degree of mismatch between donor and recipient, a low nucleated cell dose, and T-cell depletion of the donor product. Patients who experience graft failure may be retransplanted after additional immunosuppressive conditioning, but mortality from infection caused by prolonged neutropenia is significant.

Infections

After engraftment of the donor HSCs, donor-derived cells reconstitute the recipient's immune system. This is usually a rapid process after autologous transplant but is more prolonged after allogeneic transplant and may be further delayed in a recipient who develops GVHD and requires additional immunosuppression. During the early period after HSC infusion, neutropenic patients are at risk for bacterial infection, fungal infection, and infection with respiratory viruses. After engraftment, allogeneic recipients are at risk for viral infection, particularly reactivation of herpes viruses such as cytomegalovirus. Late infectious complications are mainly seen in allogeneic recipients, in whom a major risk factor is chronic GVHD. International consensus guidelines on the management of infections posttransplant have recently been published.[24]

Regimen-Related Toxicity

A number of early and late posttransplant complications are related to the conditioning regimen as well as previous therapies and pretransplant comorbidities. These include pneumonitis, sinusoidal obstruction syndrome, hemorrhagic cystitis, growth impairment, and endocrine abnormalities and are described in Chapter 110.

Secondary Malignancies

After HSCT, recipients have a two- to sevenfold increased risk of developing a secondary neoplasm, with the most frequently seen malignancies being EBV-related posttransplant lymphoproliferative disease (EBV-PTLD), therapy-related AML and myelodysplasia, and a variety of solid tumors.[25,26] As discussed earlier, autologous transplant recipients are at risk of developing therapy-related MDS and AML because of previous therapy as well as transplant conditioning. Recipients of allogeneic transplant have an increased incidence of both PTLD and solid cancers.[25,26]

Treatment of Relapse

Relapse remains a major cause of treatment failure after HSCT for hematologic malignancies, and present treatment options are

inadequate.[27] Maneuvers that are commonly used are withdrawal of immune suppression, donor lymphocyte infusions, chemotherapy, and second transplants. Chemotherapy may induce some responses but rarely results in long-term disease control. Increasing knowledge of the molecular basis of graft-versus-tumor responses has stimulated interest in the use of immunotherapy to treat relapse. Infusion of unmanipulated donor lymphocytes can result in significant clinical responses in patients with relapsed CML, but responses are less frequent in other hematologic malignancies.[28] Current research is focusing on targeting minor antigens differentially expressed on hemopoietic cells or lineage-specific antigens, such as Wilm's Tumor 1 (WTI), preferentially expressed antigen of melanoma (PRAME), or proteinase 3.[29] Other immunotherapy approaches under investigation include the administration of antitumor vaccines, NK cells, or immune effectors genetically modified with artificial receptors targeting surface antigens such as CD19 or CD30.[30]

FUTURE DIRECTIONS

An ongoing challenge is to delineate the indications for transplant as new drugs are incorporated in primary therapies for many hematologic malignancies and as risk factors continue to be redefined by new information from genetic sequencing and proteomics studies. The wider use of reduced-intensity transplant offers the prospect of using such transplants as a platform for immunotherapy, and transplant will likely be integrated more closely with other cell therapies such as infusions of NK cells, cytotoxic T cells, and regulatory T cells. The question of optimal stem cell source for patients who lack a matched sibling or 10/10 matched unrelated donor is an open issue as novel regimens to improve outcomes are being evaluated for cord and haploidentical transplants. Finally, there is a need for comparative effectiveness studies that include quality of life measures to compare transplant with other therapeutic options.

CHAPTER 105

INDICATIONS AND OUTCOME OF ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION FOR HEMATOLOGIC MALIGNANCIES IN ADULTS

Parameswaran Hari and Mary Horowitz

Thomas et al[1] first reported long-term leukemia-free survival (LFS) after human leukocyte antigen (HLA) identical sibling hematopoietic stem cell transplantation (HSCT) in some patients with refractory acute leukemia in the 1970s. Since then, allogeneic HSCT has evolved to become a frequently used and effective therapy for many hematologic malignancies. Changes in both HSCT and non-HSCT therapy have modified the indications and applicability of HSCT over time. In chronic myeloid leukemia (CML), HSCT (once the mainstay for cure) is now largely supplanted by molecularly targeted therapy. In recent years, especially after the advent of reduced intensity conditioning in the late 1990s, allogeneic HSCT is increasingly used in older patients and as an effective salvage strategy for patients with lymphoma or myeloma not responding to chemotherapy or autologous HSCT. Transplant-related mortality (TRM), although steadily declining, still remains a challenge. General principles, indications, and optimal timing of allogeneic HSCT for hematologic malignancies and long-term outcomes after HSCT are discussed in this chapter.

Allogeneic HSCT involves administration of a preparative regimen of chemotherapy, immune suppressive drugs, and/or radiation followed by infusion of donor hematopoietic cells. Most patients then receive prolonged (several months) therapy with immune suppressive drugs to prevent or treat graft-versus-host disease (GVHD). The purpose of the preparative or conditioning regimen is twofold: to eradicate malignant cells and to eliminate host immune cells capable of rejecting donor cells. The ability to restore hematopoiesis with donor HSCs permits the administration of substantially higher (myeloablative) doses of cytotoxic therapy than is otherwise possible. Although originally regarded primarily as a way of rescuing patients from therapy-induced bone marrow (BM) aplasia, it is now accepted that graft-versus-tumor (GVT) effects conferred by alloreactive donor cells contribute substantially to cancer eradication and relapse prevention.

PATIENT POPULATION

Accompanying the growth of HSCT, a coordinated, international effort evolved to collect and analyze data on transplant outcomes through the International Bone Marrow Transplant Registry (IBMTR), established in 1972. The IBMTR affiliated with the U.S. National Marrow Donor Program (NMDP) in 2004 to become the Center for International Blood and Marrow Transplant Research (CIBMTR). CIBMTR currently collects data on HSCT outcomes from more than 400 transplant centers worldwide. Approximately 5500 allogeneic transplants performed in patients 18 years of age and older were reported to the CIBMTR in 2009. These data show hematologic malignancies (and premalignant conditions) to be the most common indications for allogeneic HSCT. Acute myeloid leukemia (AML) accounted for 36% of allogeneic HSCTs, acute lymphoblastic leukemia (ALL) for 11%, CML for 3.5%, chronic lymphocytic leukemia (CLL) for 5%, and Hodgkin and non-Hodgkin lymphomas for 18% (Fig. 105-1).

Improved immunosuppression and supportive care and reduced intensity conditioning allowed increased use of allogeneic HSCT for older adults in recent years. Only 4% of allogeneic HSCT recipients from 1987 to 1992 were older than 50 years of age. In 2009, 38% were older than 55 years and 9% were 65 years or older. Allogeneic transplantation in patients without HLA-identical siblings was facilitated by establishment of large unrelated donor registries. In 1987 to 1992, fewer than 10% of HSCTs for hematologic malignancies used unrelated donors; in 2009, this figure was greater than 55%. More transplantation in older adults and increasing use of unrelated donors were the main reasons for the steady growth in allogeneic HSCT over the past 5 years.

CONDITIONING REGIMENS

Historically, conditioning regimens included myeloablative doses of cytotoxic drugs with or without radiation with the dual purpose of tumor cell kill and host immunosuppression. Myeloablative regimens for hematologic malignancies often involve a combination of cyclophosphamide (commonly 60 mg/kg/day for 2 days) and total-body irradiation (TBI) (8-15 Gy, single or fractionated doses). Many regimens substitute busulfan (typically, 4 mg/kg/day for 4 days orally or 3.2 mg/kg/day intravenously) in place of TBI. Posttransplant survival rates with cyclophosphamide and TBI and with cyclophosphamide and busulfan are similar, but there may be advantages for TBI-containing regimens in ALL. Other drugs such as etoposide, melphalan, and cytarabine are sometimes added to or substituted for cyclophosphamide or busulfan in a variety of regimens in efforts to provide better, generally disease-specific, antineoplastic activity. Large prospective trials comparing the efficacy of these regimens are lacking. A CIBMTR study suggested better outcomes in ALL in second complete remission (CR2) with either higher doses of TBI or substitution of cyclophosphamide by etoposide in a standard dose TBI regimen.

High-dose or myeloablative conditioning regimens are associated with significant risk of regimen-related toxicity. Toxicity can be minimized and efficacy improved with careful pharmacokinetic monitoring of certain drugs (e.g., busulfan).[2] Another strategy for lowering TRM is by reducing the dose intensity of the conditioning regimen. This approach uses lower doses of drugs and radiation to facilitate donor cell engraftment and relies more on GVT effects to eradicate malignant cells. The lower doses of cytotoxic agents produce less host tissue damage and less inflammatory cytokine secretion, resulting in less regimen-related morbidity and mortality and, with some regimens, less GVHD. Use of reduced-intensity conditioning regimens greatly increased the applicability of allogeneic HSCT in patients ineligible for HSCT with conventional myeloablative regimens because of age or comorbidities. The development of these novel conditioning regimens produced a major change in practice in the past decade (Fig. 105-2).

The latest consensus criteria published by the CIBMTR distinguish between myeloablative, reduced-intensity, and nonmyeloablative regimens based on the likelihood of the regimen to produce toxicity to the recipient BM (Table 105-1).[3] Myeloablative regimens produce profound and usually irreversible pancytopenia within 1 to 3 weeks and are usually fatal in the absence of stem cell rescue. Nonmyeloablative regimens cause minimal cytopenia and do not necessarily require stem cell rescue for hematopoietic recovery. Reduced

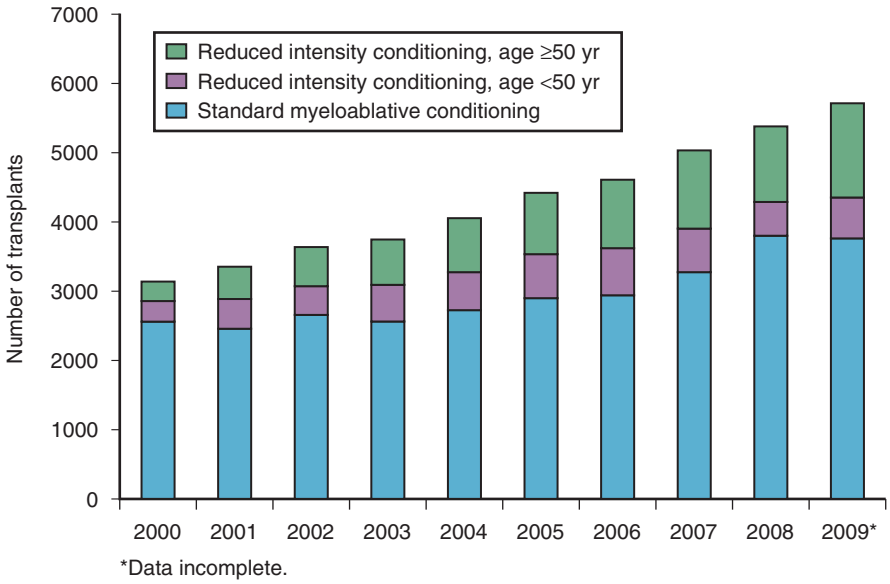

Figure 105-2 CONDITIONING REGIMEN INTENSITY AND PATIENT AGE—CHANGING TREND OVER TIME.

intensity regimens are an intermediate category not fitting well in either of the above because they produce pancytopenia that may recover without stem cell rescue but that is prolonged and, in clinical practice, requires stem cell support. It is important to recognize that these definitions are not based on the biologic effect of the transplant.

Reduced-intensity regimens induce less immune compromise in the immediate post-HSCT setting because the duration and depth of neutropenia are reduced and host-derived immunocompetent cells are not immediately eliminated. Additionally, the faster recovery of a more robust and complex T-cell repertoire and less organ toxicity make reduced-intensity regimens attractive for patients ineligible for conventional high-dose regimens because of advanced age or comorbidities.[4] Whether these benefits outweigh the risks of potentially reduced antitumor effects in patients eligible for high-dose conditioning regimens remains an important research question.

It is generally accepted that reduced intensity regimens allow HSCT to be done in some patients who will not be offered HSCT with myeloablative conditioning. For example, in the United States, the proportion of transplantations done in patients older than 60 years increased from fewer than 5% before 2000 to 12% in 2004 to 2008. Two-thirds of the latter patients received reduced-intensity conditioning regimens. The Seattle consortium described the outcomes of 372 "older" patients (ages 60-75 years) receiving very low-intensity nonmyeloablative regimens.[5] Increasing age was not associated with an increase in organ toxicity or GVHD, and the 5-year survival rate of the entire cohort was 35%. However, reduced-intensity regimens are increasingly used in patients of all ages receiving both related and unrelated donor transplants, as shown in Fig. 105-2. In 2009, about 30% of allogeneic transplantations for hematologic malignancies in patients between 18 and 55 years used reduced-intensity regimens.

Despite the growing popularity of lower intensity conditioning, large retrospective database studies from the European Group for Blood and Marrow Transplantation (EBMT) and CIBMTR (summarized in Table 105-2) have generally failed to show a definite survival advantage resulting from the use of such conditioning regimens. Disappointingly, reduction in TRM seems to be accompanied by a higher risk of cancer recurrence. Because the distribution of conditioning regimens in registry studies reflects physician choice or patient selection bias, it is difficult to know how comparable patients are who receive high- versus reduced-dose regimens and whether, even with multivariate analysis, all confounding factors are considered. Randomized trials are needed to gauge the true impact of regimen intensity. The Blood and Marrow Transplant Clinical Trials Network (BMT CTN) is conducting a phase III study of high- versus reduced-intensity conditioning before HSCT in AML or myelodysplastic syndrome (MDS).

Table 105-1 Consensus Definition of Conditioning Regimen Intensity

Myeloablative Conditioning (MAC)
PROFOUND CYTOPENIA; NOT LIKELY TO RECOVER WITHOUT HEMATOPOIETIC CELL RESCUE
Total-body irradiation ≥5 Gy single dose or ≥8 Gy fractionated
Busulfan >8 mg/kg orally or intravenous equivalent
Nonmyeloablative
MINIMAL CYTOPENIA; AUTOLOGOUS RECOVERY OF HEMATOPOIESIS LIKELY EVEN WITHOUT TRANSPLANT
Total-body irradiation ≤2 Gy ± purine analogue
Fludarabine + cyclophosphamide ± antithymocyte Globulin
Fludarabine + cytarabine ± idarubicin
Cladribine + cytarabine
Total lymphoid irradiation + antithymocyte globulin
REDUCED-INTENSITY CONDITIONING
Regimens that are intermediate between the above categories

Adapted from Bacigalupo A, Ballen K, Rizzo D, et al: Defining the intensity of conditioning regimens: working definitions. *Biol Blood Marrow Transplant* 15:1628, 2009.

GRAFT SOURCES

The sources of hematopoietic cells for transplantation, historically donor BM, now also include blood hematopoietic cells collected by leukapheresis and, more recently, umbilical cord blood. Grafts from BM, peripheral blood, and cord blood differ in the total numbers of cells available, the proportion of pluripotent stem cells to lineage-committed late progenitor cells, and the characteristics of immune reactive cells. BM is the primary source of allogeneic donor cells for transplantation in children, and peripheral blood is the main source in adults (Fig. 105-3). Among all allografts, umbilical cord blood is used for nearly 30% of transplants in children (younger than 20 years). The proportion of transplantations in adults using cord blood grafts increased from about 2% in 2004 to 6% in 2009.

The CIBMTR and the EBMT have examined long-term outcomes after peripheral blood versus BM grafts from HLA-identical siblings in adults with acute and chronic leukemia. The first report, with a median follow-up of 1 year, showed higher chronic GVHD rates in patients receiving peripheral blood grafts. Among patients transplanted for advanced leukemia, those receiving peripheral blood grafts had lower TRM and higher LFS rates. Long-term follow-up data (median, >6 years) were obtained for the patients who were alive at the time of the initial report. Consistent with the initial report, chronic GVHD was more frequent after peripheral blood transplantation than after BM transplantation; relapse rates were similar in the two groups. There was an LFS advantage for peripheral blood graft recipients for advanced CML (33% vs. 25%) but a disadvantage in those with CML in the first chronic phase (41% vs. 61%); long-term

Table 105-2 Retrospective Registry-Based Comparisons of NMA/RIC vs. Myeloablative Allogeneic Hematopoietic Stem Cell Tansplantation

Group	Disease	Donor	*n* RIC vs. MAC	TRM RIC vs. MAC	Relapse	Comments
EBMT[33]	MDS or sAML >50	MUD 39%	315 vs. 407	32% vs. 44% at 4 years	41% vs. 33% at 4 years	Survival 31% at 4 years. RIC predicted for greater relapse but lower TRM in multivariate model. Wide variety of different conditioning regimens used.
EBMT[34]	MM	MUD 12%	320 vs. 196	24% vs. 37% at 2 years	27% vs. 54%	TRM lower after RIC but relapse risk is double.
EBMT[35]	AML	Sibling	215 vs. 621	22% vs. 32% at 3 years	45% vs. 27% at 3 years	Relapse rate higher and TRM lower in RIC but OS similar (41% vs. 45%) in both groups.
EBMT[36]	CLL	MUD 22%	73 vs. 82	19% vs. 26%	28% vs. 11%	Similar TRM but higher relapse risk after RIC.
EBMT[37]	HL	MUD 13%	89 vs. 79	23% vs. 46% at 1 year	57% vs. 30%	Relapse rate higher and TRM lower in RIC but OS similar.
CIBMTR[38]	Follicular NHL	Sibling	88 vs. 120	23% in both at 1 year	17% vs. 8%	RIC associated with higher risk of relapse but similar TRM but lower KPS impacted on TRM. OS was similar.
EBMT[39]	ALL	Sibling	127 vs. 449	21% vs. 29%	32% vs. 38%	TRM lower after RIC but higher relapse rate. LFS similar to MAC
CIBMTR[40]	AML or MDS	MUD or sibling	1448 vs. 3731	3-year TRM similar	Lower risk of relapse in myeloablative	Overall and disease-free survival was highest for myeloablative group.

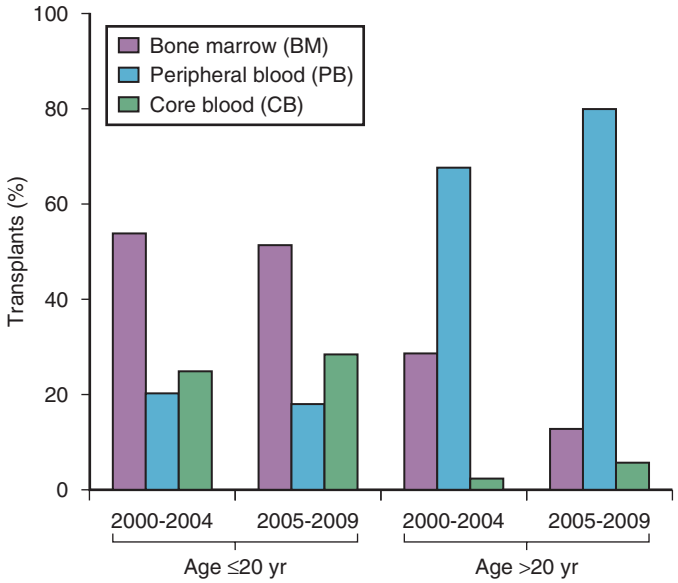

Figure 105-3 ALLOGENEIC STEM CELL SOURCES, BY DONOR TYPE VERSUS DONOR AGE, 2000 TO 2009.

LFS was similar with peripheral blood and BM in patients with acute leukemia. A meta-analysis using data from nine randomized trials of related donor peripheral blood versus BM transplants[6] suggested that patients receiving peripheral blood grafts had faster engraftment, a lower relapse rate if transplanted for hematologic malignancy and higher overall and disease-free survival if transplanted for late-stage disease. However, peripheral blood was also associated with a significantly increased risk of extensive chronic GVHD and conferred no survival advantage for patients with early stage disease. In the unrelated donor setting, a recent CIBMTR analysis of 917 transplants facilitated by the NMDP suggested that survival is similar with BM and peripheral blood grafts but that chronic GVHD is more frequent with peripheral blood. A large prospective randomized trial of 550 unrelated BM versus peripheral blood grafts for hematologic malignancies conducted in the United States by the BMT CTN was recently completed and shows similar findings—no difference in 2-year survival but a higher incidence risk of chronic GVHD in patients receiving peripheral blood.[7]

ALTERNATIVE DONOR TRANSPLANTS

A major obstacle to allogeneic HSCT is donor availability for the majority (70%) of adult patients without an HLA-identical sibling. At this time, identification of a 7/8 or 8/8 HLA-A, B, C, DRB1 allele matched adult donor is possible for about 90% of U.S. patients of white European ancestry, about 70% of those of Asian or Hispanic ancestry, and about 60% of those of African ancestry[8] (see Chapter 106). The unrelated donor search process can be time consuming, raising the risk of disease progression before transplantation can be performed. As a source of HSCs for unrelated donor transplantation, umbilical cord blood offers several advantages (see Chapter 108). It is readily available and entails no risk to the donor. Current data also indicate that HLA-matching criteria for cord blood transplantation need not be as stringent as for adult donor transplantation, greatly increasing the likelihood of finding a suitably matched graft for most patients. The major drawback of cord blood transplants is the limited number of cells in each cord blood unit, leading to slower rates of hematopoietic recovery compared with BM or peripheral blood grafts.

Numbers of cord blood transplants have increased steadily, especially in children but also in adults. Comparative data on cord blood versus adult donor transplantation come from registry studies. A CIBMTR analysis compared HLA-matched (at the allele level for A, B, C, and DRB1) BM transplants with matched and mismatched (intermediate resolution for A and B, allele level for DRB1) cord blood transplants in children with leukemia. The highest survival was in children receiving HLA-matched cord blood, although this group was small. There was no difference in outcome between HLA-matched BM and 5/6 HLA-locus matched cord blood transplants, providing the cord blood nucleated cell dose was greater than 3×10^7/kg body weight of recipient. A retrospective two-center comparative study demonstrated similar 5-year LFS after double cord blood unit, HLA-matched related donor, and HLA-allele matched or 1-antigen mismatched unrelated donor transplantation. At many experienced centers, unrelated donor and cord blood searches are simultaneously performed to ensure timely availability of a graft.

Comparisons of cord blood transplants in adults[9] consistently suggest slower hematopoietic recovery but less GVHD with cord blood grafts. Comparison of adult leukemia patients receiving cord blood versus matched unrelated BM or peripheral blood cell grafts indicated that LFS after cord grafts was comparable with that of 8/8 and 7/8 allele-matched BM or peripheral blood grafts. Results from these studies generally suggest that a one or two HLA-antigen mismatched cord blood graft of appropriate cell dose is an acceptable alternative for patients with hematologic malignancies who need HSCT but do not have an HLA-identical adult donor. Based on current evidence, cord blood grafts in adults are indicated in those without 8/8 matched unrelated donor availability or when transplantation is needed urgently. Patients without a single unit of adequate size may receive 2 units to units to facilitate engraftment.[10] Other approaches to facilitate engraftment with limited cord blood cell doses, including ex vivo cell expansion techniques, are in trials.

Human leukocyte antigen haploidentical donor HSCT (mismatched at 3 loci HLA A, B, and DR; usually parents, siblings, or children of patients) is another option for patients without matched sibling or unrelated donors (see Chapter 107). Despite the potential benefit of a strong GVT effect, the risk of severe GVHD has limited the applicability of haploidentical HSCT. Newer intense immunosuppressive strategies, graft T-cell depletion, and the use of post-transplantation cyclophosphamide have improved the safety of haploidentical transplants. Immediate donor availability and the potential to select donors with a favorable killer immunoglobulin receptor (KIR) phenotype that enhances antileukemia activity are advantages. The BMT CTN conducted two parallel multicenter phase 2 trials in patient with leukemia or lymphoma and no suitable related donors using either double cord blood units or HLA-haploidentical donor BM grafts (BMT CTN 0603) after reduced-intensity conditioning.[10] Survival at 1 year was similar: 54% after cord blood HSCT and 62% after haploidentical BM. Incidences of TRM and relapse after cord blood grafts were 24% and 31%, respectively; corresponding incidences after haploidentical BM grafts were 7% and 45%. Another approach combines a cord blood unit with a haploidentical T cell–depleted peripheral blood graft. Early hematopoietic recovery derives from the haploidentical graft but is later replaced by cord blood cell engraftment.

GRAFT VERSUS MALIGNANCY EFFECTS

Substantial laboratory and clinical evidence indicates that alloreactive cells exhibit potent anticancer activity (see Chapter 109). Barnes and Loutit studied leukemic mice treated with high-dose TBI and compared those receiving syngeneic and allogeneic BM infusions. Mice receiving syngeneic BM died quickly of leukemia; those receiving allogeneic cells survived longer but eventually developed fatal GVHD. Importantly, the allografted mice had no evidence of leukemia at death. Several canine and murine experiments reproduced these results.[11] Mathé and colleagues proposed the term *adoptive immunotherapy* for the antitumor effect of allogeneic cells. Antitumor effects could be specific (i.e., after sensitization of the donor or the donor's cells to antigens present on malignant cells) or nonspecific (i.e., associated with GVHD, an immune reaction of donor lymphocytes against normal and malignant host cells presumably triggered by differences in histocompatibility antigens).[12] The term

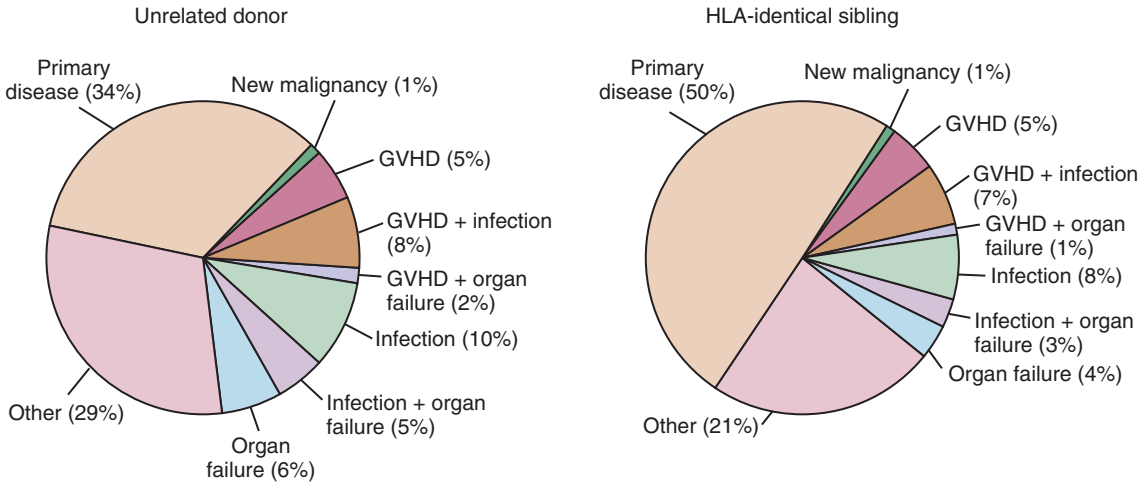

Figure 105-4 CAUSES OF DEATH AFTER TRANSPLANTATION, 2008 TO 2009. *GVHD,* Graft-versus-host diseases.

graft-versus-leukemia (GVL) was coined by Bortin and coworkers[11] to indicate the adoptive immunotherapeutic effect of transplanted allogeneic hematopoietic cells against leukemia cells. In some animal models, the GVL effect could not be distinguished from GVHD, but in others, the two were separable. Clinical evidence for the importance of GVL in eradicating tumor includes (1) a lower incidence of leukemia relapse in allograft recipients with acute or chronic GVHD than in those without GVHD,[12] (2) higher relapse rates after identical twin versus allogeneic HSCT,[12] (3) higher relapse rates after T cell–depleted transplants,[12] (4) durable cytogenetic and molecular remissions induced after posttransplant relapse by infusion of donor leukocytes without other antileukemia therapy,[13,14] and (5) durable remissions achieved after very low doses of conditioning agents (e.g., 200 cGy TBI) and allogeneic HSCT.[15] GVT effects are associated with GVHD, and measures that prevent or suppress GVHD may allow more relapse, but significant anticancer effects are demonstrable even in the absence of clinically significant GVHD, especially in AML and CML. The efficacy of immune-mediated antitumor effects varies by disease; they are most evident in myeloid leukemias and some subtypes of lymphoma.

The role of natural killer (NK) cells in the posttransplant setting is of increasing interest (see Chapter 102). After HSCT, donor-derived NK cells promote engraftment; reduce the risk of GVHD; enhance immune reconstitution; and decrease the risk of relapse, especially in AML.[16] In the physiologic state, NK cells can engage and kill target cells lacking major histocompatibility (HLA) class I molecules. This function is regulated by signaling through the killer-cell immunoglobulin-like receptor (KIR) family. In the allogeneic setting, lack of expression of the inhibitory KIRs' ligand on the recipient's leukemic cells can trigger donor NK cell alloreactivity against leukemia. The KIR family represents a second immunogenetic system inherited independent of HLA that can affect transplant outcomes, especially relapse-free survival in AML. It has been proposed that in the setting of HSCT for AML, KIR genotyping be used in addition to HLA typing by selecting donors with favorable KIR haplotypes.[17] In the setting of haploidentical and T cell–depleted HSCT for myeloid malignancies, donor–recipient KIR ligand mismatching is associated with favorable outcomes in some studies.

PROGNOSTIC FACTORS

Although allogeneic HSCT has efficacy in hematologic malignancies, the procedure carries a substantial risk of morbidity and mortality. TRM may result from toxicity of the pretransplant conditioning regimen to the lung, liver, and other organs or complications of cytopenia, GVHD, and infection related to delayed immune reconstitution, especially in the setting of GVHD or its treatment. The risk of TRM may be 30% or higher in adults receiving unrelated donor transplantation. Additionally, many patients have recurrence of their malignancy despite intensive conditioning and GVL. Primary causes of death after allogeneic transplantation for hematologic malignancy are shown in (Fig. 105-4). The prognosis of transplant recipients is influenced by several factors associated with risk of TRM or cancer recurrence or progression.

Donor Factors

Historically, TRM rates were lower after HLA-identical sibling than after other related or unrelated donor transplants because of less graft failure, faster immune reconstitution, and less GVHD. Considerable progress has been made in reducing the risk of TRM after both HLA-identical sibling and alternative donor HSCT. For matched sibling donor HSCT in AML in CR1, the incidence of TRM decreased from 29% in 1985 to 1989 to about 15% in 2000 to 2004. For unrelated donor HSCT, the incidence of TRM in 1990 to 1994 was 39%, which decreased to 31% by 2000 to 2004.[18] Among alternative donor transplants, those from more closely HLA-matched donors tend to have lower risks of GVHD and TRM. Donor–recipient HLA mismatching is associated with an increased risk of posttransplant complications, including graft rejection, acute and chronic GVHD, and mortality; risks increase progressively with multiple HLA mismatches. With modern molecular HLA typing techniques (allowing selection of more closely HLA-matched donors) and current GVHD prevention strategies, the difference in TRM between HLA-matched sibling and unrelated donor transplantation has narrowed (Fig. 105-5). Using data reported to the CIBMTR in 2009, TRM at day 100 for adults with acute leukemia receiving allografts was 10% overall, 8% for those transplanted in remission, and 14% for those transplanted with active disease. At 1 year, the TRM was 20% overall and 17% and 24% for those in remission and with active disease at HSCT, respectively. The causes of death in the first 100 days posttransplant mainly relate to the primary disease, GVHD, infection, and end-organ damage.

Adoption of molecularly defined HLA matching techniques, calcineurin inhibitor–based GVHD prophylaxis, fungal prophylaxis with azoles, leukocyte reduction of blood products, newer assays for viral reactivation, and pharmacokinetic testing of conditioning drugs are some of the major innovations that have impacted TRM. Stratification and scoring of patient comorbidity and genome-wide analysis for polymorphisms that predict for susceptibility to TRM are currently being explored to develop tailored approaches to HSCT that may make it safer.

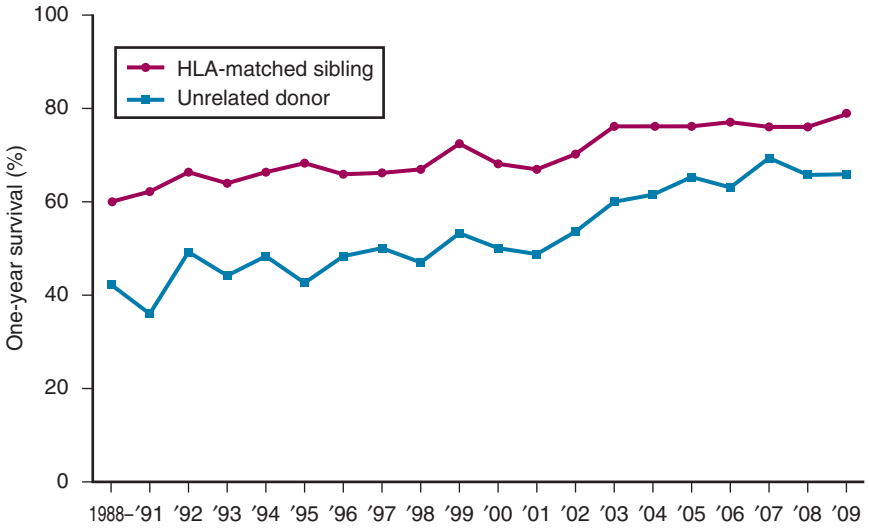

Figure 105-5 ONE-YEAR SURVIVAL AFTER MYELOABLATIVE HEMATOPOIETIC STEM CELL TRANSPLANTATION IN YOUNGER PATIENTS (RELATED VS. UNRELATED DONOR). *HLA,* Human leukocyte antigen.

Timing of Transplantation

In general, HSCT outcomes are better when transplantation is done earlier in the course of a malignancy (see box on Timing of Hematopoietic Cell Transplantation and Transplant Referral). Transplantation for advanced disease is associated with higher risks of both relapse and TRM. High TRM in the setting of advanced disease likely reflects patients' poorer clinical status and the cumulative effects of more extensive prior treatment. Because some hematologic malignancies have an excellent prognosis with nontransplant therapy (e.g., children with standard risk ALL or adults with acute promyelocytic leukemia), appropriate timing of transplantation requires consideration of likely outcomes with transplant and nontransplant therapies. However, even when not used as first-line therapy, transplantation should not be inordinately delayed because patients with refractory disease or severe complications from extensive prior therapy are unlikely to benefit. For patients with diseases potentially curable by allografting, appropriate timing of transplantation should be considered early in planning management strategies. This includes determining the availability of suitable related or unrelated donors. The American Society for Blood and Marrow Transplantation (ASBMT) has developed evidence-based guidelines based on current clinical practice and available literature (available online at http://www.asbmt.org; see boxes on American Society of Blood and Marrow Transplantation Consensus Policy for Allogeneic Hematopoietic Cell Transplantation and Transplant Referral: Guidelines for Transplant Consultation for Hematologic Malignancies).

Timing of Hematopoietic Cell Transplantation and Transplant Referral

- HSCT outcomes are better when performed earlier in the course of hematologic malignancies.
- HSCT for advanced disease is associated with higher TRM and relapse.
- Appropriate timing of HSCT requires consideration of likely outcomes with nontransplant and transplant therapies and the suitability of patient to undergo HSCT.
- Even when not considered as front-line therapy, inordinate delay in HSCT is to be avoided.
- For patients who are potentially curable by allogeneic HSCT, consideration of HSCT should be addressed early in the treatment plan. This includes HLA typing and identification of suitable donors.

Patient- and Disease-Related Factors

Transplant-related mortality is lower and, consequently, survival is higher, in patients who are young, cytomegalovirus (CMV) antibody screen negative, and have good performance scores and no active infection.[19] Age still poses a significant barrier to application of allogeneic HSCT because older patients are at significantly higher risk of regimen-related toxicity and GVHD. Consequently, the median age of transplant recipients is substantially lower than the median age at diagnosis of the diseases for which transplantation is done. Factors associated with increased likelihood of relapse or progression after conventional therapy also predict increased risk of posttransplant relapse or progression. Importantly, patients whose disease does not respond to conventional therapy are significantly less likely to have durable remissions after transplantation than those with responsive disease. However, HSCT may cure a significant proportion of patients with diseases considered incurable with non-transplant therapy.

CLINICAL RESEARCH IN ALLOGENEIC TRANSPLANTATION

The number of HSCTs performed in the United States is increasing at a rate of approximately 5% per year. Only a minority of patients have their transplantations performed in clinical trials. Challenges unique to the field of HSCT, such as small numbers treated at individual centers, the wide variety of indications, and multiple competing risks in the peritransplant period, make it difficult to perform single-center studies. To overcome these challenges, in the United States, a national multicenter transplant study network has been established. The BMT CTN has thus far launched 27 multicenter trials and accrued more than 4000 patients.

Although clinical trials focus on short- and intermediate-term outcomes, there is also a need for long-term follow-up of transplant recipients. Outcomes registries, such as those maintained by the CIBMTR and the EBMT, are important in facilitating additional clinical research. The CIBMTR maintains a large database of clinical information on the outcome of HSCTs performed in 500 transplant centers in nearly 50 countries. The database includes information on more than 350,000 transplant recipients. Data quality and consecutive registration are ensured through extensive computer checks and on-site audits. Data collection is through a web-based data entry program. Some important questions, such as results of HSCT in specific patient groups and rare diseases, analysis of prognostic factors, evaluation of new transplant regimens, comparison of HSCT with nontransplant therapy, and defining intercenter variability in practice and outcome, are difficult to address in randomized trials and can be studied using registry data. Analysis of outcomes after transplantation

American Society of Blood and Marrow Transplantation Consensus Policy for Allogeneic Hematopoietic Cell Transplantation*

Disease State	*Policy Regarding Allogeneic Transplantation*
AML in adults[30]	1. Survival advantage is established for allogeneic HSCT vs. chemotherapy for patients younger than age 55 years with high-risk cytogenetics. 2. Insufficient evidence to routinely recommend allogeneic HSCT for patients with intermediate-risk cytogenetics. 3. No survival advantage for allogeneic HSCT in patients younger than age 55 years with low-risk cytogenetics. 4. Insufficient data to make a recommendation for the use of myeloablative regimens for patients older than age 55 years. 5. Insufficient data to make a recommendation for reduced-intensity conditioning (RIC) followed by HSCT vs. chemotherapy. 6. For patients in second complete remission, allogeneic HSCT is recommended if there is an available donor.
ALL in adults[26]	1. In first CR, allogeneic HSCT as first-choice therapy is appropriate for all risk groups. In younger patients (younger than 35 years), with standard risk, Ph-negative ALL, HSCT results in superior survival compared with chemotherapy. In older (older than 35 years) patients, with standard risk Ph-negative ALL, higher TRM diminishes survival benefits of HSCT. 2. In second CR, allogeneic HSCT is recommended over chemotherapy. 3. There is similar survival after related and unrelated donor HSCT for ALL. 4. RIC may produce similar outcomes to myeloablative, but available data are limited. RIC is appropriate only for patients with ALL in remission and unsuited for myeloablative conditioning.
Diffuse large B-cell lymphoma[31]	1. Survival outcomes are equivalent for autologous and allogeneic HSCT; neither option is recommended over the other. Comparison between the two techniques is biased by different patient selection criteria. 2. Based on limited data, RIC is an acceptable alternative for selected patients who cannot tolerate a myeloablative regimen.
Follicular non-Hodgkin lymphoma[32]	3. Autologous vs. allogeneic HSCT: There are insufficient data to recommend one option over the other because comparison between the two techniques is biased by different patient selection criteria. 4. Based on limited data and expert opinion, RIC is an acceptable alternative approach to myeloablation. 5. Based on expert opinion, matched unrelated donor transplants are considered as effective as matched related donor transplants.
Myeloma	6. Autologous transplant is preferred over allogeneic HSCT based on current evidence. Studies are ongoing to further evaluate the role of allogeneic HSCT.

Transplant Referral: Guidelines for Transplant Consultation for Hematologic Malignancies*

Adult Acute Myeloid Leukemia

High-risk AML, including:

- Antecedent hematologic disease (e.g., myelodysplasia)
- Treatment-related leukemia
- Induction failure

First complete remission with poor-risk cytogenetics or high-risk molecular markers

Second complete remission and beyond

Adult Acute Lymphoblastic Leukemia

First complete remission up to age 35 years

High-risk ALL in those older than age 35 years, including:

- Poor-risk cytogenetics (e.g., Philadelphia chromosome or 11q23 rearrangements)
- High WBC (>30,000-50,000/cu mm) at diagnosis
- CNS or testicular leukemia
- No CR within 4 weeks of initial treatment
- Induction failure

Second complete remission and beyond

Chronic Myeloid Leukemia

- No hematologic or minor cytogenetic response 3 months after imatinib initiation
- No complete cytogenetic response 6 to 12 months after imatinib initiation
- Disease progression, accelerated phase, or blast crisis

Non-Hodgkin Lymphoma

Follicular Lymphoma

- Poor response to initial therapy
- Initial remission duration <12 months
- Second relapse
- Transformation to diffuse large B-cell lymphoma

Diffuse Large B-Cell Lymphoma

- First or subsequent relapse
- First CR for patients with high or high intermediate IPI
- No CR with initial treatment

Mantle Cell Lymphoma

- After initial therapy

Hodgkin Lymphoma

No initial CR

First or subsequent relapse

Multiple Myeloma

After initiation of therapy

At first progression

*Available online at http://www.marrow.org/PHYSICIAN/Medical_Education/Quick_Reference/index.html?src=mdguidelines.

needs an understanding of statistical methodologies such as multistate modeling. Such models involve competing risk problems such as the study of relapse versus death in remission or the complex interrelationships among engraftment, transplant complications (e.g., infection or GVHD), and primary events such as death or relapse.[20] Outcomes registries also provide a platform to analyze the availability, access, and economics of HSCT. A biospecimen repository maintained by the NMDP and associated with the CIBMTR database allows the linkage of clinical and immunologic data for analysis and has led to important insights into transplant immunobiology.

LONG-TERM SURVIVAL AFTER ALLOGENEIC TRANSPLANTATION

Most deaths related to HSCT occur within the first 2 years. However, an analysis of 2-year survivors found that compared with age- and nationality-matched death rates, subsequent survival was still inferior for HSCT recipients.[21] Overall, 85% of 2-year survivors were still alive at 10 years post-HSCT. Late relapse was the major cause of late deaths and was associated with advanced disease at HSCT. Older age and GVHD were the other major predictors of late mortality.

There are now about 250,000 persons surviving 5 years or more after transplantation, and that number is growing. Most 5-year survivors are well, off all immune suppression, and leading normal lives. However, transplant recipients remain at risk for late complications, including late infections, cataracts, abnormalities of growth and development, thyroid disorders, chronic lung disease, and avascular necrosis. There is also an increased incidence of leukemias, myelodysplasia, and solid tumors in transplant recipients compared with the general population. Lifelong surveillance is necessary, as is increased awareness of late complications among the many nontransplant physicians who will care for these patients. Recommended long-term follow-up of HSCT recipients is summarized in the box Recommended Practices for Allogeneic Transplant Recipients in Long-Term Follow-up.

DISEASE-SPECIFIC INDICATIONS FOR ALLOGENEIC TRANSPLANTATION

Acute Myeloid Leukemia

There is general agreement that most patients younger than the age of about 60 years who fail conventional therapy and who have good performance status are best treated with allogeneic transplantation if an appropriate related or unrelated donor is available (see Chapter 60). HSCT is not recommended for those with favorable risk cytogenetics with the possible exception of those with additional mutations in the KIT gene in the setting of core binding factor AML.

The National Comprehensive Cancer Network (NCCN) guidelines,[22] widely used to guide cancer therapy in the United States, distinguishes between patients younger than 60 versus those older than 60 years. Among younger patients, the panel recommended a postremission strategy based on factors such as the expected relapse rates with high-dose cytarabine therapy alone, salvage treatment options at relapse, and patient-specific comorbidities that predict for TRM. The guidelines uniformly endorsed allogeneic HSCT from related or unrelated donors including cord blood HSCT, in first remission for patients with unfavorable cytogenetic or molecular abnormalities, therapy-related AML, or prior myelodysplasia. Also, there was consensus that patients with high-risk features such as an elevated leukocyte count at presentation and those needing more than 1 cycle to achieve a remission be considered for allogeneic HSCT in first remission. Among those older than 60 years, the recommendation was to consider HSCT as an early option in those achieving a complete response and as treatment for induction failure only in patients with low-volume residual disease. For relapsed AML, HSCT was recommended irrespective of age but only after a complete remission was achieved or in the context of a clinical trial. For patients with acute promyelocytic leukemia, the recommendation was to reserve allogeneic HSCT for patients with persistent relapsed disease despite salvage therapy.

The ASBMT's evidence-based policy for allogeneic HSCT in AML recommends HSCT in the relapse setting (after achievement of a second complete remission) and in patients with poor-risk cytogenetics in first remission. The ASBMT guidelines did not routinely recommend allogeneic HSCT for patients with intermediate-risk cytogenetics, myeloablative conditioning for patients older than age 55 years, or use of reduced-intensity conditioning. The NMDP guidelines for transplant evaluation recommend an HSCT consultation for all patients with high-risk AML (defined as AML preceded by another hematologic disorder, treatment-related leukemia, and primary induction failure), those with poor prognostic markers by cytogenetics or molecular studies, and patients in second or subsequent remission.

A systematic review of various national guidelines found the following[23]:

1. Consistent recommendations that patients with relapsed or refractory disease or high-risk cytogenetics be considered for HSCT.
2. Consistent recommendations that patients with good prognosis cytogenetics receive HSCT only after failure of nontransplant therapy.
3. Inconsistent recommendations for patients with intermediate-risk disease or without a family donor regarding transplantation in the first remission.
4. Lack of consensus regarding the efficacy of reduced-intensity conditioning.
5. Most national guidelines recommend a risk-based approach to guide selection of chemotherapy versus transplant approaches using factors such as patient age, comorbid conditions, disease phenotype at diagnosis, and the number of cycles of therapy before remission.

Acute Lymphoblastic Leukemia

Allogeneic HSCT in first remission from related or unrelated donors is generally accepted as the most effective available therapy for patients with Philadelphia chromosome (Ph)-positive ALL. For adults with Ph-negative ALL, the appropriate timing of HSCT is more controversial despite the largest prospective study (MRC/ECOG) and a meta-analysis suggesting a survival advantage for those assigned to transplant in first remission.[24,25] Allogeneic transplantation is currently considered by NCCN expert consensus as the best curative therapy for adult patients with high risk features such Ph+ ALL or those with a poor response to initial induction therapy and among adults with t(4;11) ALL. A recent evidence-based policy statement from the ASBMT recommended allogeneic HSCT for young (younger than 35 years) adults in first remission irrespective of risk group and for ALL in second or higher remission. Related and unrelated donor HSCT were recommended as being similar in outcomes.[26] For those without suitable matched adult donors, cord blood grafts should be considered.

Chronic Myeloid Leukemia

In general, HSCT is indicated for patients whose initial presentation is in blast phase and should be considered for those with a suboptimal response or relapse while taking tyrosine kinase inhibitors (TKIs) (see Chapter 66). HSCT is also a consideration for patients who have bcr-abl mutations that predict for TKI nonresponse. It is important to establish a monitoring plan for early signs of progression and for mutation screening because outcomes are significantly better if HSCT is performed before transformation to advanced disease. Definitions of suboptimal response and failure with TKIs and guidelines

for monitoring have been developed.[27] In 2011, the NCCN taskforce recommended consideration of HSCT in chronic phase CML for those receiving second-line TKI therapy after failing primary TKI therapy. In this setting, failure to achieve complete hematologic response at 3 months or any cytogenetic response at 6 to 12 months or at least a partial cytogenetic response at 18 months after initiation of therapy or a cytogenetic relapse at any time on therapy were considered indications to proceed to HSCT. For those with CML progression to advanced phase or blast crisis, TKI-based therapy for induction followed by HSCT was recommended. European experts have evolved very similar recommendations and consider HSCT the only curative option for patients in accelerated or blast phase, patients with T315I mutation, and those in chronic phase failing or intolerant of second-generation TKIs.

Chronic Lymphocytic Leukemia

Current NCCN guidelines recommend allogeneic HSCT in chronic lymphocytic leukemia for those of younger age with high-risk disease (TP53 deletion, 11q deletion) in the front-line setting, and for those with CLL relapsing shortly after initial response (<2 years)

irrespective of cytogenetics. The EBMT consensus group[28] has recommended allogeneic HSCT as a reasonable treatment option for younger patients with nonresponse, partial responses, or relapse (within 12 months) after purine analogue therapy. Patients who relapse within 24 months after having a response to purine analogue–based combinations and patients with TP53 abnormalities and those with Richter transformation requiring treatment are also considered candidates for transplant evaluation.

Diffuse Large B-Cell Lymphoma

The NCCN guidelines recommend autologous transplantation (after second-line chemotherapy) as the treatment of choice for relapsed or refractory diffuse large B-cell lymphoma. Allogeneic HSCT is a consideration in the context of clinical trials, and in selected situations, such as mobilization failure and persistent BM disease.

Follicular Lymphoma

A systematic review by the ASBMT noted the lack of high-quality evidence regarding indications for allogeneic HSCT in follicular lymphoma. The consensus panel recommended autologous HSCT for relapsed disease or transformed follicular lymphoma. In the allogeneic setting, reduced-intensity conditioning was considered an acceptable alternative to myeloablative regimens. The panel found no differences in outcomes between the use of HLA-identical sibling donors and matched unrelated donors. Given the efficacy of rituximab-based salvage treatments and autologous HSCT for follicular lymphoma, allogeneic HSCT is generally used for patients who have failed, are likely to fail, or are unable to proceed to salvage autologous HSCT. However, late application of allogeneic HSCT may be less effective, especially for chemotherapy-refractory disease. The NCCN guideline panel recommended autologous transplantation in second or third remission as a standard consolidative strategy for relapsed follicular lymphoma. Allogeneic HSCT was a consideration for highly selected patients and those with histologic transformation to a higher grade (especially in the context of a clinical trial).

Mantle Cell Lymphoma

In recent years, reduced-intensity conditioning is the standard approach for allogeneic HSCT for mantle cell lymphoma. Current NCCN guidelines recommend autologous transplantation as an adjunct to initial therapy in eligible patients because it has the potential of establishing durable remission.[29] Expert opinion is that allogeneic HSCT has a limited role as consolidation in chemotherapy-sensitive disease. Given the poor prognosis of recurrent mantle cell lymphoma and the curative potential of allogeneic HSCT, it is a reasonable option for patients relapsing after upfront autologous transplantation and those with chemotherapy-refractory disease.

T-Cell Lymphoma

The NCCN guidelines recommend consideration of allogeneic HSCT in the relapsed or refractory setting in T-cell lymphoma. In cutaneous T-cell lymphoma, allogeneic HSCT is considered in the setting of progressive or refractory stage IIB to IV disease after failure of biologic agents and at least one line of chemotherapy.

Hodgkin Lymphoma

The NCCN guidelines currently consider allogeneic HSCT in progressive or relapsed Hodgkin lymphoma as a category 3 recommendation (major disagreement) and recommend that this treatment should therefore ideally be performed as part of a clinical trial.

Multiple Myeloma

The NCCN guidelines consider allogeneic HSCT with myeloablative conditioning as an accepted option in the setting of a clinical trial, in those responding to primary therapy, and those with primary progressive disease. The guidelines did not recommend allogeneic HSCT with nonmyeloablative conditioning alone as an option. Reduced-intensity conditioning with allogeneic HSCT after autologous HSCT was considered a category 2A recommendation (reflecting uniform NCCN consensus based on lower level evidence, including clinical experience, that the recommendation is appropriate). Allogeneic HSCT in the relapsed setting after a prior autograft was considered a grade 3 recommendation, reflecting major disagreement.

CHAPTER 106

UNRELATED DONOR HEMATOPOIETIC CELL TRANSPLANTATION

Effie W. Petersdorf and Claudio Anasetti

The outcomes of unrelated donor hematopoietic cell transplantation (HCT) have greatly improved as a result of better understanding of the diversity of genes that give rise to host-versus-graft (HVG) and graft-versus-host (GVH) allorecognition. Development of robust typing methods that define functional variation of human leukocyte antigen (HLA) and killer immunoglobulin-like receptor (KIR) genes have greatly accelerated understanding of gene–gene interactions that lead to graft failure, graft-versus-host disease (GVHD), and graft-versus-leukemia (GVL). Elucidation of which HLA molecules are the ligands for KIR receptors of natural killer (NK) cells and discovery of the pivotal role played by NK alloreactivity are opening up new avenues for potential antitumor therapy. Continued growth of registries of volunteer donors worldwide now provides the potential for identifying suitable donors for up to 65% of white patients in need of a transplant. The major challenges are to increase the safety and efficacy of unrelated donor HCT therapy through improved prevention and treatment of GVHD while leveraging control of leukemia through GVL effects. For unrelated HCT to be more widely applied to patients of diverse ethnic and racial backgrounds, more information on permissible HLA mismatches is needed so that mismatched donors can be safely used when matched donors are not available. This chapter chronicles genotyping methods used for donor selection and the clinical results of unrelated donor HCT in the era of DNA typing for HLA and KIR genes. Double cord blood transplantation (CBT) permits almost every patient a transplant when matched cell sources are not available. The relative merit of CBT compared with mismatched unrelated donor transplantation has not been elucidated. Readers are invited to read Chapter 108 for more detailed information on CBT.

VOLUNTEER REGISTRIES

The field of allogeneic transplantation has witnessed a rapid growth in the use of unrelated donors over the past 15 years. In a Center for International Bone Marrow Transplant Research (CIBMTR) survey, unrelated donor transplants accounted for the largest increase among all transplants and for 51% of the allogeneic transplants in the United States. A total of 16,974 transplants were performed yearly, of which 39% were allogeneic and 20% from unrelated donors (http://www.CIBMTR.org). The primary indications for unrelated donor HCT were leukemia (acute myeloid leukemia [AML], acute lymphoblastic leukemia [ALL], myelodysplastic syndrome [MDS], lymphoma, chronic myeloid leukemia [CML], multiple myeloma [MM], and chronic lymphocytic leukemia [CLL]) and nonmalignant disorders. In Europe, unrelated donor transplants also constitute 51% of all allogenic transplants, and they are performed for treatment of leukemia (63%), MDS and myeloproliferative disorders (8%), lymphoma (16%), and nonmalignant disorders (8%).[1] Approximately one-third of allogenic transplants are performed for patients ages 50 years and older.

Unrelated HCT has been made feasible by the establishment of registries of volunteer donors worldwide. The Anthony Nolan Appeal was the first effort to demonstrate the feasibility of donor recruitment. Now known as the Anthony Nolan Research Institute, this registry was the first to promote access to HLA-matched bone marrow (BM) donors for patients around the world. In the United States, early efforts for donor recruitment were spearheaded by individual centers. Growing interest in unrelated donor HCT led the U.S. Congress to authorize the creation of a national registry comprising a network of donor centers, transplant centers, and a national coordinating center through the Transplant Act of 1984. Two years later, a federal contract to establish a national registry was awarded to the National Marrow Donor Program (NMDP) (http://www.nmdp.org). In the Netherlands, Professor Jon J. van Rood led the Europdonor Foundation in the collection of HLA data from donor registries around the world and in the formation of a database of HLA phenotypes known as Bone Marrow Donors Worldwide (BMDW) (http://www.bmdw.org). Continued growth in registry size worldwide has increased the chances that well-matched donors can be identified. The NMDP registers 25,500 new donors each month and more than 300,000 each year (http://www.marrow.org). Today, more than 8 million donors are available through the NMDP, and more than 18 million donors are available through international cooperative agreements with registries around the world (http://www.worldmarrow.org).[2] With this database of 18 million donors, North American white patients have a 62% chance of identifying an 8/8 matched unrelated donor. This number increases to 89% if the donor selection criteria are relaxed to 7/8. The situation is not as favorable for patients of non-European white background. For African Americans, the likelihood of finding an 8/8 matched donor is only 15% and improves to 63% with 7/8 donors. These statistics emphasize that although the total number of donors is climbing, the challenges for the future remain achieving the ideal optimal registry size and composition to improve the odds that every patient in need of a transplant has at least one suitable donor.

The median time from initiation of a formal unrelated donor search to a request for a donation is 51 days (http://www.marrow.org). Although more than half of all U.S. patients who initiate a search will have 10 or more suitably matched NMDP donors, the efficiency of the search process is highly dependent on the racial and ethnic background of the recipient and the composition of the registry. A Dutch study of 549 unrelated donor searches conducted between 1987 and 2000 showcased the differences between median search times for patients of Northwestern and non-Northwestern European descent.[3] Whereas almost 60% of Northwestern European patients received a transplant within a median time of 4.4 months from the start of the search, only 32% of non-Northwestern European patients were able to identify suitable donors, and half did not have a compatible donor. For all patients, the efficiency with which the unrelated donor search is conducted is critical, and guidelines for planning transplantation as well as approaches for surmounting the unique challenges of finding donors are available (http://www.asbmt.org/policystat/policy.html).

DONOR EVALUATION AND SELECTION

Selection of unrelated donors includes consideration for the level of the HLA tissue type match with the recipient and the presence of recipient antidonor antibodies, which place the patient at high risk for nonengraftment. Criteria other than HLA are considered for

donor selection when more than one HLA-identical match is available for a given patient. An NMDP analysis designed to study donor variables associated with transplant outcome examined 6978 transplants performed between 1987 and 1999.[4] Improved recipient survival and disease-free survival (DFS) were observed with use of young BM donors; these transplant recipients experienced lower risks of both acute and chronic GVHD. With each increasing decade of donor age, the risk of acute and chronic GVHD increased by 10%. This study did not find any effects of donor gender on engraftment, acute GVHD, or survival. However, transplantation from parous female BM donors was associated with increased risk of chronic GVHD. Among female parous donors, the relative risk was 1.19 with a history of a single pregnancy and increased to 1.40 with two or more pregnancies. In general, larger (male) donors provide larger BM and peripheral blood stem cell (PBSC) doses compared with smaller (female) donors. Donor ABO blood type does not affect the risk of GVHD or mortality. In an NMDP analysis of 7043 transplants performed between 2000 and 2004, the donor–recipient HLA match status and younger donor age were the two variables significantly associated with clinical outcome. In an NMDP analysis of transplants performed through 2007, donor HLA mismatching was confirmed to be significantly associated with transplant outcome, trumping the cytomegalovirus (CMV) serostatus of the donor.[5]

Evaluation of unrelated donors includes a screening medical history, physical examination, and laboratory testing for risks associated with transmissible elements akin to blood transfusion donors. Special focus is placed on risks of transmission of hepatitis, human immunodeficiency virus (HIV), malaria, West Nile virus, transmissible spongiform encephalitis (Creutzfeldt-Jacob disease), and Chagas disease. Donor screening includes blood tests for HIV 1 and 2, hepatitis B virus, hepatitis C virus, *Treponema pallidum,* human T-cell lymphotrophic virus I and II, and CMV.

The importance of a "backup" donor has been increasingly recognized. In a Dutch study of 502 unrelated donor evaluations, 46 were cancelled with 78% deferred because of medical reasons and 22% deferred because of nonmedical reasons.[6] In half of the cases for which a backup donor was already identified, the delay in scheduling the transplant was less than 2 weeks. However, when no backup donor was available, the median delay to transplant was 18 weeks. Identification of backup donors is particularly important for patients with high-risk hematologic malignancies, whose disease tempo does not allow delays in transplantation.

Table 106-1 Common Definitions in Human Leukocyte Antigen Genetics

Term	Definition	Example
Allele	Unique sequence of an HLA gene defined by molecular methods	DRB1*04:01 allele is a unique sequence defined as DR4 by serologic methods
Antigen	Antibody-defined protein	DR4 antigen is a serologically defined protein product of an HLA gene
Haplotype	HLA genes inherited as a chromosomal unit	HLA-A1, HLA-B8, HLA-DR3 is a common haplotype among white populations
Genotype	Molecularly defined HLA allele or sequence	Genotypically matched donor and recipient are identical for the HLA alleles at a given HLA gene (e.g., HLA-DRB1*04:01)
Phenotype	Serologically defined HLA protein or antigen	Phenotypically matched donor and recipient share the same HLA antigen (e.g., HLA-DR4)

HLA, Human leukocyte antigen.

Table 106-2 Polymorphism of Human Leukocyte Antigen Genes

	Antigens	Alleles
HLA-A	24	1698
HLA-B	50	2271
HLA-C	9	1213
HLA-DRB1	15	975
HLA-DQB1	9	158
HLA-DPB1	6	149

PROCESS OF IDENTIFYING A SUITABLE UNRELATED DONOR

Human Leukocyte Antigen Typing and Donor Matching in the DNA Era: Genetics of the Human Leukocyte Antigen Complex

The advent of molecular techniques has made possible the definition of unique sequence variants (alleles) that encode each HLA molecule that is recognized by an antibody (antigen; Table 106-1). Polymorphism ensures that a large array of foreign peptides can be presented to the immune system by HLA molecules. As of July 2011, more than 1698 HLA-A, 2271 HLA-B, 1213 HLA-C, 975 HLA-DRB1, 158 HLA-DQB1, and 149 HLA-DPB1 alleles have been defined in diverse human populations (http://www.ebi.ac.uk/imgt/hla; Table 106-2). HLA nomenclature was recently modified to accommodate the steady discovery of new human variants (http://www.ebi.ac.uk/imgt/hla). The HLA prefix is followed by a hyphen to separate the HLA prefix from the gene name (e.g., HLA-A). The gene is listed followed by an asterisk to separate the gene from the unique sequence (HLA-A*). The unique sequence name embodies up to four kinds of information, each delimited by a colon. The first set of numbers after the asterisk and before the first colon correspond to the serologic antigen equivalent (e.g., HLA-A*02 refers to sequences of the HLA-A2 antigen family). The second set of numbers provides the unique protein that correspond to the subtype (HLA-A*02:101). The third set of numbers indicate synonymous substitutions (HLA-A*02:101:01). The last series of numbers give information on noncoding variation often denoting expression (HLA-A*02:101:01:02 N). Letter suffixes are used to denote null alleles (N), low cell surface expression (L), a soluble secreted molecule not present on the surface of the cell (S), a cytoplasmic product not expressed on the cell surface (C), a protein with aberrant expression (A), and a sequence of questionable expression (Q). This new nomenclature has no limits on the number of digits for each of the four categories and in this way obviates the need for constant renumbering.

DNA genotyping was adopted as the standard technique for selection of HLA-matched unrelated donors because unrelated individuals who are matched for HLA antigens may not necessarily share the same HLA sequences. If HLA alleles can be expressed in any combination and if inheritance of alleles were random, then the total estimated number of possible five-locus HLA-A, HLA-B, HLA-C, HLA-DRB1, and HLA-DQB1 genotypes would be more than 1×1023. Clinical experience demonstrates that some patients have been able to find a matched donor even in a relatively small file of unrelated donors. Donor identification is successful because HLA alleles are found in association with each other at an observed frequency that exceeds their expected frequency, a phenomenon known as linkage disequilibrium (LD). The probability of identifying a matched donor for a given patient is higher when the patient and donor share

Table 106-3 Definition of Matching for Alleles and Antigens

Designation	Match Status	Examples*	Donor	Recipient
Allele	Antigen matched	HLA-B*44	HLA-B*44	
Allele	Matched	HLA-B*44:02	HLA-B*44:02	
Allele†	Mismatched	Antigen matched	HLA-B*44	
Allele	Mismatched	HLA-B*44:02	HLA-B*44:03	
Antigen‡	Mismatched	Antigen mismatched	HLA-B*44	HLA-B*27
Allele	Mismatched	HLA-B*44:02	HLA-B*27:05	

*Human leukocyte antigen (HLA) alleles and antigens are designated according to the World Health Organization Nomenclature for Factors of the HLA System.
†Defined by DNA sequencing.
‡Defined by serology.

a similar ethnic background. Linked HLA genes are inherited from each parent as a haplotype in classical Mendelian fashion (see Assessment of Human Leukocyte Antigen Haplotypes later). HLA gene and haplotype frequencies provide important data for estimating optimal registry size and composition (http://www.allelefrequencies.net).

Given the polymorphism of allele sequences that encompass variants of a single serologically defined antigen, it is not surprising that antigen-matched donor and patient pairs may differ for their alleles (Table 106-3). A study by the NMDP defined the extent of allele mismatching among serologically typed recipients and their transplant donors.[7] Among HLA-A, HLA-B, HLA-DRB1 serologically matched pairs, as many as 29% encoded allele mismatches at HLA-A, HLA-B, or HLA-DRB1; 89% of HLA-A, HLA-B, HLA-DRB1 allele-identical pairs encoded additional mismatches at HLA-C and HLA-DP. Early donor selection criteria did not include consideration for HLA-C, so many donors who were serologically or even sequence matched for HLA-A and HLA-B antigens were later found to be mismatched at the HLA-C locus. The overall frequency of allele mismatching is lower if the recipient has a common haplotype. Because the frequencies of HLA alleles and haplotypes reflect the ethnicity and race of the patient and donor population, donor–recipient HLA mismatches can be ethnogeographically distinct (http://www.allelefrequencies.net). In white transplant populations, for example, donor–recipient allele disparity is frequent for the A*02, B*27, B*35, B*39, and DRB1*04 allele families.

HUMAN LEUKOCYTE ANTIGEN TYPING METHODS

Serology and Cellular Assays

Serologic reagents have served as the gold standard for HLA antigen typing since the early 1960s. Development of standardized tissue typing reagents and methods of nomenclature for HLA genes have been facilitated by a series of 15 international histocompatibility workshops (Table 106-4). Serologic typing methods use a complement-dependent microcytotoxicity assay with alloantisera containing antibodies against polymorphic HLA specificities. Whereas a public specificity is shared by distinct HLA molecules, a private specificity is unique to a single HLA molecule. HLA molecules can share one or more public epitopes and differ for private epitopes. The combination of HLA antigens of an individual defines their phenotype, and the alleles define their genotype. All serologically defined alloantigens have been characterized at the allele level; however, not all sequenced-defined alleles have an equivalent phenotype studied by serology. Hence, a nomenclature has been developed to translate serologically defined antigens and DNA-defined alleles.

The most commonly used cellular assay for the class II region is the mixed lymphocyte culture (MLC), in which disparity between the donor and the recipient for the antigens encoded by HLA class II region genes (also known as the HLA-D region) leads to lymphocyte activation and proliferation. Although the strength of the proliferation measured in an MLC correlates roughly with the degree of HLA-D region incompatibility, MLC is poorly predictive of GVHD and therefore has limited clinical utility for donor selection.

The limiting dilution assay is a technique for determining the frequency of donor antihost cytotoxic T-lymphocyte precursors and helper T-lymphocyte precursors. These assays have proved useful in predicting the risk of GVHD and mortality before transplantation in some reports and may provide a means for selecting a suitable unrelated donor when more than one equally matched donor is available. High frequencies of cytotoxic T-lymphocyte precursors have been observed with class I donor–recipient mismatching; helper T-lymphocyte precursor has been shown to detect class II disparity. The frequency of donor cytotoxic T-lymphocyte precursor reactivity against recipient targets is correlated with the risk of acute GVHD after unrelated donor HCT when ex vivo or in vivo T-cell depletion is used for GVHD prophylaxis. In T-cell–replete transplantation, significant associations between frequency of cytotoxic T-lymphocyte precursors and acute GVHD have not been identified.

DNA Methods

The advent of polymerase chain reaction (PCR) in the 1980s revolutionized donor typing and matching and has greatly accelerated understanding of the HLA barrier in transplantation. Guidelines for typing volunteer donors using DNA-based methods are available. To transition from serologic to DNA-based methods, development of dictionaries of HLA alleles and antigen equivalents has become a necessity because many donors in the registries have been typed only by serologic assays. Interpretation and use of molecular typing data for donor search and selection has required the development of informatics programs.

Low-resolution DNA-based typing methods can define groups of alleles that are serologic equivalent (e.g., HLA-A*02 is DNA defined and is equivalent to HLA-A2 that is serologically defined). Intermediate-resolution DNA typing methods provide additional information but not to the level of the complete DNA sequence that distinguishes one allele from another (e.g., the information is sufficient to delineate one group of alleles that include HLA-A*0201 and another that include HLA*0205 but cannot definitely assign the allele). High-resolution typing defines the unique DNA sequence of an allele (e.g., HLA-A*0201). The term "6/6" matched refers to recipients and donors who share the same low-resolution-defined HLA-A, HLA-B, and HLA-DR genes. The term "8/8" refers to high-resolution matching at the four loci HLA-A, HLA-B, HLA-C, and HLA-DRB1. When HLA-DQB1 is added, "10/10" refers to high-resolution matching at the five loci. When HLA-DPB1 is added, "12/12" refers to donor–recipient pairs that are allele matched at all six genetic loci.

Several PCR-based HLA typing approaches are widely used by clinical tissue typing laboratories in support of unrelated HCT

HCT, Hematopoietic cell transplantation; *HLA,* human leukocyte antigen; *HTC,* homozygous typing cells; *KIR,* killer immunoglobulin-like receptor; *MHC,* major histocompatibility complex; *MLC,* mixed lymphocyte culture; *NK,* natural killer; *PCR,* polymerase chain reaction; *RFLP,* restriction fragment length polymorphism; *SNP,* single nucleotide polymorphism.

programs. The sequence-specific primer method uses a panel of primers to amplify the HLA locus or alleles. The PCR products are electrophoresed on a gel, and assignment of an HLA type is made by examining the composite pattern of positive and negative PCR reaction methods.

The sequence-specific oligonucleotide probe hybridization (SSOPH) method uses a solid phase support to immobilize PCR-amplified products. Nonradioactive-labeled oligonucleotide probes are allowed to hybridize to the support. Whereas probes with sequences complementary to the target DNA will hybridize, probes with as few as one nucleotide difference will fail to hybridize. Alternatively, SSOPH methods can use probes that are immobilized to the solid phase support and allow PCR-amplified target DNA to hybridize to the support.

A variation of the SSOPH method is oligonucleotide array technology. Arrays can simultaneously query multiple regions of polymorphisms in many HLA genes. Oligonucleotide probes can be designed to all four potential nucleotides, thereby enabling detection of new sequence polymorphisms with the same sensitivity and specificity as sequencing-based typing. Redundancy of probe sequences allows combinations of alleles to be distinguished in heterozygous individuals. Commercial platforms are now available and provide quality-controlled reagents for high through-put genotyping.[8-10] Finally, sequencing methods provide high resolution of HLA alleles and are the definitive method for characterizing novel HLA sequences.

ASSESSMENT OF THE VECTOR OF MISMATCHING

The "vector" or "direction" of HLA compatibility between a donor and a recipient has biologic relevance in defining the risks of graft failure and GVHD. The concept of the vector was first demonstrated in cases of haploidentical related mismatched transplantation and defines HVG and GVH alloreactivity. Whereas the presence of donor alleles not shared by the recipient determines HVG allorecognition, the presence of recipient alleles not shared by the donor provides the immunologic basis for GVH allorecognition (Table 106-5). "Bidirectional" mismatching refers to the situation in which both HVG and GVH vectors are present at a given HLA locus. "Unidirectional" mismatching describes the situation in which either the donor or the recipient is homozygous for the same allele at the mismatched locus. A unidirectional GVH vector mismatch occurs when the donor is homozygous and the recipient is heterozygous and shares one allele with the donor (e.g., patient DRB1*01:01, *04:10 vs. donor DRB1*01:01, *01:01). A unidirectional HVG vector mismatch

Table 106-5 Vector of Mismatch

Vector	Definition	Examples	
		Donor	Recipient
HVG	Presence of donor alleles not present in the recipient	DRB1*01:01,04:01* DRB1*01:01,04:01†	DRB1*01:01,04:10 DRB1*01:01,01:01
GVH	Presence of recipient alleles not present in the donor	DRB1*01:01,04:01* DRB1*01:01,01:01†	DRB1*01:01,04:10 DRB1*01:01,04:10

GVH, Graft versus host; *HVG,* host versus graft.
*These combinations contain bidirectional (both HVG and GVHD) mismatch vectors.
†Unidirectional mismatches.

occurs when the patient is homozygous and the donor is heterozygous and shares one allele with the patient (e.g., patient DRB1*01:01, *01:01 vs. donor DRB1*01:01, *04:01). Clinical outcomes analyses that evaluate the association between HLA disparity and risk of graft failure or GVHD should specify the vector of incompatibility that is used to define the comparison groups.

ASSESSMENT OF HUMAN LEUKOCYTE ANTIGEN HAPLOTYPES

Patients who are candidates for allogeneic transplantation undergo a pedigree analysis to determine the availability of potential HLA genotypically identical siblings who could serve as a donor. The family study, which includes typing of the propositus' mother, father, and all full siblings, provides an internal verification of the patient's HLA haplotypes. Because HLA genes segregate in classical Mendelian fashion, the probability that a sibling inherits the same parental haplotypes is 25% (genotypically identical). The probability that a sibling inherits one identical paternal or maternal haplotype plus one nonshared haplotype is 50% (haploidentical). The probability of inheriting neither of the same haplotypes is 25% (complete mismatch).

When no related donor is available or suitable, a search for an unrelated donor is initiated. A search of all available international registries today includes consideration of more than 11 million donors worldwide (http://www.nmdp.org; http://www.worldmarrow.org). In the assessment of every unrelated donor, matching for each HLA genetic locus allele is considered. However, gene-by-gene identity for HLA-A, HLA-B, HLA-C, HLA-DR, and HLA-DQ between two unrelated individuals does not necessarily signify that the HLA alleles are linked on the same chromosomal haplotype. Hence, it is possible for two unrelated individuals who share the same HLA genotype to have different HLA haplotypes. The clinical significance of haplotype matching is described next.

CLINICAL IMPORTANCE OF DONOR HLA MATCHING IN CASES OF UNRELATED DONOR HCT

The first successful human allogeneic BM transplantations were performed in 1968. Early clinical experience in allogeneic transplantation identified both HLA and non-HLA factors as important in defining posttransplantation complications. Donor HLA mismatching was identified as a risk factor for graft failure after HCT from relatives. Non-HLA factors associated with an increased risk of graft failure included transplantation of a lower BM cell dose, use of T cell–depleted BM, and transplantation of BM from a cross-match–positive donor (presence of antidonor lymphocyte antibodies in the patient's serum pretransplant). HLA mismatching was also shown to increase the incidence and severity of acute GVHD.

Use of HLA-matched unrelated donors as the source of BM was first applied in the case of a patient with severe aplastic anemia. Durable engraftment and immunologic reconstitution were early barriers to successful unrelated donor HCT. As clinical experience matured and tissue typing methods became more robust, unrelated donor HCT was established as a therapeutic approach for treatment of hematologic disorders when an HLA-identical sibling is not available. DNA-based methods have become established as the gold standard for HLA testing because serologically identical recipients and potential unrelated donors can be mismatched for one or more alleles that are identified by DNA testing methods. Retrospective analysis of transplant donors and recipients that test the hypothesis that allele disparity confers biologic significance on transplant outcome should include examination of pairs that are fully typed for HLA-A, HLA-B, HLA-C, HLA-DRB, HLA-DQB1, and HLA-DPB1 at the sequence level. Many non-HLA variables have an impact on the same clinical endpoints that are also affected by HLA disparity. Hence, multivariable models should adjust for all clinical variables that are known to affect outcome. Finally, the study should have sufficient statistical power to detect a significant difference in outcome when one truly exists. Very large numbers of transplants are required to adjust for HLA and non-HLA variables (see box on Criteria for an Interpretable Study on the Role of Human Leukocyte Antigen Matching in Cases of Unrelated Donor Transplantation). Studies meeting these criteria have demonstrated that patients had superior DFS after HLA-matched unrelated HCT. When allele-matched donors are not available, the criteria for prioritization of mismatched donors come into focus. The current criteria for donor selection are as follows. (1) When feasible, "8/8" HLA-A, HLA-B, HLA-C, and HLA-DRB1 matching predicts for best patient survival. (2) When a matched donor cannot be identified, use of a donor mismatched for a single allele can be considered. Under these circumstances, matching for HLA-DQB1 should also be considered because mismatch for DQB1 alone seems forgiving, but mismatch for DQB1 plus another locus appears to increase mortality. (3) Multiple mismatches are less well tolerated and should be limited. (4) Permissible HLA mismatches have been proposed as defined by polymorphism for selected HLA class I residues that participate in peptide repertoire or direct contact with the T-cell receptor. (5) HLA haplotype matching between donors and recipients may lower the risk of severe acute GVHD. (6) Polymorphisms outside of the classical HLA loci may be clinically significant (Table 106-6).

Criteria for an Interpretable Study on the Role of Human Leukocyte Antigen Matching in Cases of Unrelated Donor Transplantation

DNA-based methods have become established as the gold standard for HLA testing. Research studies aimed at defining the importance of HLA mismatching in transplant outcome ideally examine donor–recipient transplant pairs that are fully typed for HLA-A, HLA-B, HLA-C, HLA-DRB1, HLA-DQB1, and HLA-DPB1 at the sequence level. In this way, the relative risks of HLA disparity on a given clinical endpoint can be more accurately measured. Many non-HLA variables have an impact on the same clinical endpoints that are also affected by HLA disparity including whether the underlying disease is malignant or nonmalignant, whether the conditioning regimen is ablative or reduced intensity, and the specific regimen used to prevent GVHD. These nongenetic variables may contribute risks that diminish the ability to discern HLA-specific effects and require multivariate models to adjust or stratify for these variables to assess independence of HLA effects on the clinical endpoint of interest. Finally, the study should have sufficient statistical power to detect a significant difference in outcome when one truly exists. Very large numbers of transplants are required to adjust for HLA and non-HLA variables.

Table 106-6 Principles of Donor Human Leukocyte Antigen Matching Using High-Resolution DNA Typing Methods

1. When feasible, four-locus HLA-A, HLA-B, HLA-C, and HLA-DRB1 matching is optimal.
2. Although there are no "good" mismatches, HLA-C antigen mismatches are particularly detrimental.
3. Multiple mismatches are less well tolerated and should be limited.
4. Permissible HLA mismatches can be defined by specific class I and class II residues that participate in peptide repertoire or direct contact with the T-cell receptor.
5. Haplotype matching of HLA-A, HLA-B, HLA-C, HLA-DRB1 allele-identical donors and recipients may lower posttransplant risks of clinically severe acute GVHD.

GVHD, Graft-versus-host disease; *HLA,* human leukocyte antigen.

Human Leukocyte Antigen Selection Criteria for Unrelated Donors

DNA typing can uncover additional allele disparity between HLA-A, HLA-B, HLA-DR phenotypically matched unrelated donors and recipients. Both GVHD and mortality are increased with use of phenotypically matched unrelated donors compared with related donor–recipient pairs. The difference in outcome can be attributed in part to the effects of mismatching for HLA-A, HLA-B, HLA-C, and HLA-DRB1 alleles and to the degree of HLA-A, HLA-B, HLA-DRB1 haplotype identity between the donor and recipient. Routine testing of potential donors should include DNA typing for HLA-A, HLA-B, HLA-C, and HLA-DRB1 at the intermediate resolution (antigen-equivalent) level. After the best-matched unrelated donors are identified, routine testing should include allele (sequence)-level typing for these genes. When a matched donor is not available, then the number of mismatches should be limited to one or two, with a single HLA-DQB1 mismatch being the best tolerated.

HUMAN LEUKOCYTE ANTIGEN–MATCHED UNRELATED DONOR HEMATOPOIETIC CELL TRANSPLANTATION

The impact of more complete and precise donor HLA matching is dramatic. Overall survival after transplantation for treatment of AML, MDS, ALL, and CML from an 8/8 matched unrelated donor can approach the results observed after HLA-identical sibling transplantation (http://www.marrow.org). For all modalities, the underlying disease diagnosis and stage of disease at transplantation remain the most important prognostic features that affect DFS. The impact of HLA mismatching with respect to these clinical variables is coming into better focus. The development of reduced-intensity conditioning regimens has expanded the clinical indications of HCT to patients of older age and patients who have underlying medical conditions that preclude the use of myeloablative regimens. The role of HLA mismatching in growth factor-mobilized PBSC unrelated HCT has recently been clarified.[11]

In an analysis of patients transplanted for treatment of acute or chronic leukemia or NHL from HLA-identical siblings, patients positive for HLA-DR15 had lower recurrence of disease posttransplant and improved survival compared with patients who were DR15 negative.[12] Additional reports of HLA associations with GVHD risk after sibling transplantation suggest that the immunogenicity of the specific alleles may directly influence GVHD risk.[13] Because the siblings were HLA identical, these observations cannot be explained by HLA disparity. These data have significance not only in the setting of HLA-identical related HCT but also for unrelated and mismatched related donor HCT. In addition to HLA allele mismatch-specific risk after unrelated HCT, new evidence suggests that risk can arise from mismatching for HLA haplotypes (see Importance of Major Histocompatibility Complex Haplotypes later). The risk associated with haplotype mismatching after unrelated donor HCT can be assessed with haplotyping tools.

SINGLE-LOCUS MISMATCHED UNRELATED HEMATOPOIETIC CELL TRANSPLANTATION

Early studies of patients receiving HLA antigen-matched, MLC-compatible unrelated donor HCT uniformly reported a relatively high incidence of acute GVHD and transplant-related mortality (TRM) compared with transplantations from HLA-identical siblings. The possibility that undetected donor–recipient mismatching for HLA allele variants could be responsible for increased complications in cases of unrelated donor HCT suggested that the safety and success of unrelated donor transplantations could be improved by further advances in HLA typing and donor matching and prompted close examination of serologically identical unrelated transplant pairs using DNA typing methods. The HLA variation that is identifiable using DNA methods is functional. DNA-based methods can detect differences in allele sequences among serologically identical unrelated donor–recipient pairs, and the risk of mortality is increased with mismatching for a single HLA allele. Most posttransplant complications associated with donor HLA mismatching occur within the first 6 months after transplantation, but some occur quite late.

The risks of graft failure, GVHD, and mortality associated with mismatching are not contributed equivalently by all HLA loci. Because DNA-based laboratory methods were first developed for class II genes, clinical information on donor mismatching for HLA-DRB1, HLA-DQB1, and HLA-DPB1 preceded that for HLA-A, HLA-B, and HLA-C. As a result, donor selection criteria included consideration for donor class II matching in the early 1990s followed by refined criteria inclusive of class I (see box on Human Leukocyte Antigen Selection Criteria for Unrelated Donors). Early studies of class II allele matching were performed in study populations typed by serology for class I antigens. As a result, the risks attributed to DRB1 or DQB1 mismatching may have included the risk related to additional undetected class I disparities. In one of the earliest studies of patients with hematologic malignancy transplanted from HLA-A, HLA-B, HLA-DR serologically matched unrelated donors, DRB1 and DQB1 allele mismatching was associated with increased risk of severe acute GVHD. Several large studies extended the findings of class II disparity and risk of clinically significant acute GVHD. An NMDP analysis of 831 CML transplants found that the HLA-DRB1 effects were significant when class II allele matching was evaluated in a good-risk subset of patients transplanted during the first chronic phase from class I serologically matched unrelated donors.

Human Leukocyte Antigen C: Discovery of a Classical Transplantation Antigen

Among the earliest clinical observations implicating class I was the demonstration that HLA-C is capable of eliciting an alloantibody immune response.[14] HLA-C antigens could be recognized by cytotoxic T lymphocytes and present peptides to T cells. Demonstration of HLA-C as a classical transplantation antigen did not occur until the 1990s. HLA-C mismatching was identified as an independent risk factor for graft failure, particularly in patients receiving myeloablative conditioning regimens followed by T cell–replete transplantations for treatment of CML.[15] Increased risk of graft failure was also associated with HLA-A or HLA-B mismatching and low BM cell dose.

The importance of unrelated donor matching for HLA-C was confirmed by several large analyses (Table 106-7). In the NMDP study,[5] DNA from donors and recipients were typed for HLA-A, HLA-B, HLA-C, HLA-DRB, HLA-DQA1, HLA-DQB1, HLA-DPA1, and HLA-DPB1 alleles using high-resolution methods. After accounting for clinical variables and mismatching at HLA-A, HLA-B,

Table 106-7 Impact of HLA-A, B, C, DR Matching on Mortality: 8/8 Model

	Patients (*n*)	Relative Risk	95% Confidence Interval	*P* Value

*HLA-A, C, B, DRB_1.

and HLA-DR, multivariate analysis revealed that HLA-C allele disparity conferred a statistically significantly increased relative risk on mortality (Table 106-8).

Most of the historical data concerning HLA disparity and transplant outcomes were derived from BM as the stem cell source. The use of growth factor–mobilized PBSC has been widely used as the preferred stem cell source for ease of donor collection. A recent analysis of the impact of HLA mismatching in unrelated PBSC transplantation was conducted by the NMDP and CIBMTR.[7] In this series of 1933 transplants, risks associated with donor disparity at HLA-A, -C, and -B and DRB1 were defined ("8/8"). Complete matching was associated with improved 1-year survival compared with any single mismatch ("7/8"). Overall, donor HLA-C antigen mismatching was associated with the worse outcomes compared with HLA-A, HLA-B, or DRB1 mismatching. HLA-C antigen mismatching increased mortality (relative risk [RR], 1.41; $P = .0005$), lowered DFS (RR, 1.36; $P = .001$) and grades III or IV acute GVHD (RR, 1.98; $P < .0001$). HLA-C allele mismatches did not increase risks. HLA-B allele or antigen mismatches were associated with GVHD; there were no statistically significant associations of HLA-A, DRB1, or DQB1 mismatches with transplant outcomes. These data demonstrate that prospective evaluation of unrelated donors should include consideration for compatibility at HLA-C.

Models for Understanding Alloreactivity

HLA-B and HLA-DP have served as models for understanding the structural basis for allorecognition, where specific amino acid residues of class I and II molecules contribute to eliciting the immune response. Donor-derived cytotoxic T lymphocytes isolated from a patient with graft rejection selectively recognized the patient-mismatched HLA-B44 allele (B*4402 vs. B*4403), indicating that class I allele differences may evoke donor–antihost responses and supporting the hypothesis that allelic variants of the same HLA antigen can be functionally relevant.[16] A parallel story emerged for HLA-DP. Population studies have shown that HLA-DP is unique among other HLA genes because of very weak LD between HLA-DP and HLA-A, HLA-B, HLA-C, HLA-DR, and HLA-DQ. As a result, fewer than 20% of HLA-A, HLA-B, HLA-C, HLA-DRB1, and HLA-DQB1–matched unrelated donor pairs are also matched for HLA-DP. Retrospective examination of HLA-DP has required very large transplant populations so that sufficient numbers of HLA-DP matched pairs could be compared with mismatched pairs. Furthermore, the measured effects attributed to single loci in early studies likely measured additive effects of HLA-DP with HLA-A, HLA-B, and HLA-DR. HLA-DP does function as a classical transplantation antigen with respect to GVHD. Mismatching for two DPB1 allele increases the risk of acute GVHD compared with one or no HLA-DP mismatch. Analysis of the structural basis of HLA alloreactivity sheds light on specific epitopes encoded by HLA-DP exon 2 that are responsible for increased GVHD risk.[17] This study showcases the importance of functional studies side-by-side genetic analysis to better understand the residues that define alloreactivity.

The hypothesis that donor–recipient mismatching at certain amino acid substitutions in the class I HLA molecule may be associated with higher posttransplant risks compared with mismatching at other residues was first tested by Ferrara et al.[18] Amino acid mismatching at residue 116 was found to be associated with significantly increased risks of acute GVHD and TRM compared with matching at this residue. Recently, the JMDP has evaluated 5210 Japanese recipients of unrelated donor transplants to identify mismatched residues of HLA-A, -B, -C, -DRB1, -DQB1, or -DPB1 molecules that correlate with clinical outcome.[19] Analysis of each allele-defined mismatch yielded four HLA-A, one HLA-B, seven HLA-C, two HLA-DR/DQ, and two HLA-DP mismatch combinations to be significantly associated with increased posttransplant complications. Each allele was subsequently defined by its putative amino acid sequence, and all polymorphic donor–recipient mismatched positions at each locus were individually analyzed for associations. Donor–recipient mismatching for Tyr9–Phe9 of HLA-A and for Tyr9–Ser9, Asn77–Ser77, Lys80–Asn80, Tyr99–Phe99, Leu116–

Ser116, and Arg156–Leu156 of HLA-C were identified to be clinically significant. When the study group was restricted to pairs matched at HLA-C for positions 77 and 80 that define KIR ligands, donor–recipient mismatching at positions 9, 99, 156, and 163 were found to correlate strongly with GVHD risk. This study demonstrates that mismatching for positions of HLA-A or HLA-C that participate in peptide binding is functional and provides a basis for defining nonpermissive HLA allele mismatches. Of the 10 mismatch combinations associated with GVHD risk, the JMDP explored whether the same mismatch combinations were involved in both GVHD and relapse (GVL effects) or only one.[20] In a population of 4643 transplants, 10 mismatch combinations (four for HLA-C and six for HLA-DPB1) were statistically significantly associated with lowered relapse; however, only a subset were also involved in GVHD. These results suggest that HLA mismatches do not confer equivalent risks to GVHD and relapse and that approaches for separating GVH from GVL may be possible through selected HLA combinations. Statistical models have been developed to predict peptide binding of HLA molecules as an approach to predict HLA alleles that lead to diverse binding of peptide and that may consequently affect T-cell recognition of HLA and its minors.

DOES MISMATCH FOR ALLELES OR ANTIGENS POSE THE SAME RISKS?

With the availability of molecular methods for defining the HLA alleles of transplant recipients and donors, it now is possible to evaluate the impact of the location and number of mismatched amino acid residues as potential factors defining the permissibility of a mismatch. In a single-center study of graft failure after myeloablative unrelated HCT, donor–recipient mismatching for HLA-A, HLA-B, or HLA-C antigens conferred greater risk for graft failure than did single allele mismatches at these loci.[21] Recipient homozygosity for alleles or antigens was also significantly associated with graft failure among patients with a single class I antigen mismatch. Graft failure occurred in one of two homozygous recipients and in none of 47 heterozygous recipients mismatched for a single allele ($P = 0.04$), but graft failure occurred in four of five homozygous recipients and in seven of 51 heterozygous recipients mismatched for a single antigen ($P = 0.004$). The allele and antigen mismatches represented in this study population differed in the number of nonsynonymous substitutions and in the location of the mismatch in the α_1 and α_2 domains of the molecule. Single class I allele disparity encoded from 0 to 14 (median, 2) substitutions in the α_1 and α_2 domains. In contrast, single antigen mismatched pairs had involvement of one to 27 (median, 13) substitutions. These data series, highly enriched for mismatches at HLA-C, suggest that multiple mismatches for residues that affect peptide binding and T-cell receptor contact might have been instrumental in evoking T-cell responses that led to graft failure in these patients.

Two studies have examined allele and antigen mismatches in large populations and the risks conferred by each kind of mismatch on TRM and survival.[5,22] A single-center analysis from Seattle indicated that an isolated allele or antigen mismatch was similarly detrimental to survival. Among low-risk patients, no single-locus mismatch with the exception of HLA-DQ appeared tolerable. HLA-C mismatches were particularly detrimental, whether patients had low- or high-risk malignancy. An analysis by the NMDP measured risks associated with single-locus mismatches in a large population of HLA allele-typed pairs (see Table 106-8).[5] Each HLA-A, HLA-B, HLA-C, or HLA-DRB1 mismatch was found to confer a 9% to 10% lower overall survival compared with a baseline of 8/8 allele matches. Among all single-locus mismatches, disparity for HLA-A or HLA-DRB1 was associated with higher mortality rate than disparity at HLA-B or HLA-C. Mismatching at HLA-A, HLA-B, and HLA-C each was associated with an increased risk of GVHD. As in the previous NMDP analysis, allele and antigen mismatches were similarly detrimental except for the case of HLA-C, in which allele disparities did not contribute to the risk. These data are consistent with the graft failure study discussed earlier in which a predominance of HLA-C mismatches and allele disparities did not contribute to increased risk. In the recent update from the NMDP and CIBMTR,[11] only HLA-C locus mismatches showed a difference between allele and antigen mismatches; HLA-C antigen mismatches conferred a RR of 1.41 for mortality, but C allele mismatches did not increase risk. These studies demonstrate that when measuring the effects of HLA mismatching, large, well-characterized populations are needed, and variables known to affect clinical outcome should be accounted for. Avoidance of HLA-A, HLA-B, HLA-C, and HLA-DRB1 allele mismatches may lower the risks of posttransplant complications.

MULTILOCUS MISMATCHED UNRELATED DONOR HEMATOPOIETIC CELL TRANSPLANTATION

The effects of HLA disparity on risk of graft failure, GVHD, and mortality can be measured by the total number of detectable mismatches. As the number of HLA disparities increases, so does risk for these complications. In the JMDP study of 1298 patients, the overall incidence of graft failure increased with increasing numbers of mismatched HLA loci: 1.7% matched; 4.8%, 4.1%, and 4.8% of single HLA-A/B, HLA-C, and HLA-DR/DQ, respectively; 10.4%, 8.9%, and 6% in two-locus HLA-A/B plus HLA-C, HLA-A/B plus HLA-DR/DQ, and HLA-C plus HLA-DR/DQ, respectively; and 10.6% in three-locus incompatible transplants.[23] In patients who received unrelated donor HCT for treatment of CML,[21] single allele mismatch at HLA-A, HLA-B, or HLA-C did not increase the risk of graft failure compared with matched recipients (2%); however, multiple HLA-A, HLA-B, or HLA-C allele mismatches were associated with a 29% incidence of graft failure.

Quantitative effects of multiple class I, multiple class II, or simultaneous class I and II mismatching can be associated with acute GVHD risk. Pronounced effects of two-locus HLA-DRB1, HLA-DQB1 mismatching on risk of grade III and IV acute GVHD can be discerned (22% matched; 43% single-locus mismatches; 64% two-locus mismatches). In HLA-A, HLA-B, HLA-DR serologically matched unrelated pairs who received unmodified grafts, matching for both HLA-DRB1 and HLA-DQB1 reduced the rate of GVHD from 73% (any mismatch) to 38% (matched for both genes; $P = 0.02$).

JMDP data provide information on the quantitative effects of HLA mismatching on GVHD risk.[23] Not only were multiple class I disparities a risk factor for GVHD, but HLA-C disparity in the presence of mismatching at any other HLA locus (class I, class II, or both) was associated with significantly increased incidence of grades II through IV GVHD: 60.9%, 55.7%, and 64.3% for HLA-C plus HLA-A/B, HLA-C plus HLA-DR/DQ, and HLA-C plus HLA-A/B and HLA-DR/DQ, respectively, compared with 34.5%, 54.9%, 42.7%, and 34.4% for matched, HLA-A/B mismatched, HLA-C mismatched, and HLA-DR/DQ mismatched, respectively. The JMDP experience demonstrates that multilocus mismatching is associated with a decreased rate of survival. In some pediatric series, children tolerate higher degrees of disparity with use of certain immunosuppressive regimens.

IMPORTANCE OF MAJOR HISTOCOMPATIBILITY COMPLEX HAPLOTYPES AND MAJOR HISTOCOMPATIBILITY COMPLEX RESIDENT VARIATION

Currently, gene-by-gene matching between recipients and unrelated donors is performed to approximate the haplotype matching that is feasible between genotypically identical sibling pairs. However, HLA-matched unrelated donors and recipients are not related to one another; therefore, they are described as identical by state. This opens the possibility that genes other than classical HLA may be clinically

relevant. The major histocompatibility complex (MHC) is the most diverse region in the human genome known to date. More than 300 loci have been verified within the extended 7.6-megabase (Mb) MHC region have immune function.[24] Hence, current donor matching is performed for less than 5% of the total gene content of the MHC.

In addition to the classical HLA loci, the MHC is residence to the nonclassical *HLA-E, HLA-F, HLA-G, MICA,* and *MICB* genes. Data suggest a role for HLA-E in transplant outcome.[25] Increased risk for bacterial infections and corresponding TRM at day 180 post-transplant were found in recipients transplanted from HLA-E*0101,0101 homozygous unrelated donors. HLA-E*0103,0103 homozygosity among HLA-identical siblings conferred protection against acute GVHD and TRM, leading to increased overall survival. These data point to the potential involvement of the innate immune system in GVHD. New information on *MICA* in transplantation has become available.[26] In a retrospective study of 236 patients transplanted from HLA-matched and -mismatched unrelated donors, 8.4% were mismatched for *MICA*. The presence of *MICA* disparity was associated with higher risk of overall grades II to IV acute GVHD and higher gastrointestinal GVHD independent of HLA mismatching. Because the gastrointestinal epithelium is the sole organ where *MICA* is expressed, the data suggest that *MICA* serves as a classical transplantation antigen.

Mapping with microsatellite (Msat) markers was among the earliest approaches for discovering disease-causing variation in many model systems, including autoimmunity and cancer. Msats provide indirect information because Msats themselves are not functional. Their LD with putative functional genes, however, provides the basis for its application in estimating optimal donor registry size and composition and for donor selection. Studies have used Msats to query the MHC region for novel determinants. Tumor necrosis factor (TNF) variation within the class III region of the HLA complex was associated with lower survival among patients who developed GVHD.[27] These early studies provided key evidence that variation outside of the classical HLA genetic loci both exist and are potentially functional in transplantation.

More recently with the availability of a complete sequence of the MHC, mapping with the use of single nucleotide polymorphisms (SNPs) has provided investigators with a robust tool for disease mapping.[28-31] The MHC is characterized by LD of discrete segments or blocks of sequences that reside between HLA genes. Although the specific content of these blocks is under investigation, donor–recipient matching for these regions is associated with superior clinical outcome. The map of the MHC continues to be refined for both simple variation such as that represented by SNPs to more complex variation, including insertions and deletions (http://www.sanger.ac.uk/HGP/Chr6?MHC). The content of several common HLA haplotypes, including HLA-A1, B8, DR3 and HLA-A2, B DR15, showcases the extreme levels of sequence conservation over long stretches of the MHC, upward of 4 Mb in some haplotypes.[24] This work importantly shows the need for similarly dense sequence information on common as well as rare haplotypes in all ethnicities and racial populations to understand how such variation may be clinically relevant.

How can knowledge of haplotype content facilitate the discovery of new transplantation determinants? The available sequence alignments demonstrate that the classical HLA loci serve as robust markers for the undetected linked variation on the haplotype. To test the hypothesis that the HLA haplotype serves as a tool for querying such areas outside of classical loci, a novel long-range phasing technique has been developed.[32] By physically linking HLA-A with HLA-B with HLA-DR on the same strand of DNA, this technique has been applied to test the hypothesis that HLA-identical unrelated donors and recipients encode different HLA haplotypes, and furthermore, haplotype mismatching is associated with increased posttransplant risks conferred by variation that is linked to the different haplotypes.[33] In this study, a homogeneous population of HLA-A, HLA-B, HLA-C, HLA-DRB1, HLA-DQB1 allele-matched unrelated transplants were characterized using the phasing method. Of these pairs, 20% were found to have different physical linkage of HLA-A, HLA-B, and HLA-DR. Haplotype mismatching was associated with a significantly increased risk of grade III to IV acute GVHD. The increased risk of GVHD was offset by lower relapse, leading to similar overall survival. This study demonstrates that variation linked to the haplotype is functional and that the HLA haplotype can be used as a surrogate marker for GVHD risk.

Fine mapping will entail comprehensive analysis of both simple and complex MHC variation. In this way, comparative sequences analysis of common and rare haplotypes continues to be an important research area.[34] Most recently the JMDP carried out an extensive analysis of three commonly observed HLA haplotypes in their transplant population.[35] This work has provided invaluable information on the degree of conservation within and across haplotypes of the Japanese population and provides insight into the possible genetic basis for differences in GVHD risk among Japanese patients compared with white patients.

KIR RECEPTORS

Elucidation of the genetic diversity of the KIR family of genes and their functional role as receptors for HLA class I offers a novel approach for use of HLA class I mismatched donors to decrease risks of GVHD and relapse. KIRs are inhibitory or activating. Both types are expressed on NK cells and other cell types, including T cells; however, inhibitory KIRs are dominant. *HLA* and *KIR* genes are encoded on chromosomes 6 and 19, respectively, and segregate independently. However, HLA serves a dominant role in selection of the peripheral repertoire of NK cell inhibitory KIRs. Thus, HLA-mismatched siblings, haploidentical relatives, and mismatched unrelated donors have different repertoires of NK cell inhibitory KIRs. In only HLA mismatching pairs can there be the potential for "mismatched ligand." In some HLA-matched and -mismatched pairs, the recipient is missing the appropriate ligands for donor NK cell inhibitory KIR ("missing ligand"). A recipient who lacks the appropriate HLA ligand for the donor KIR will trigger NK-mediated killing of host target cells. In HCT for malignancy, such a combination is desirable because killing of target host leukemia cells would lead to a lower risk of relapse after transplantation. Some pairs of HLA-identical individuals encode distinct KIR sequences and can express distinct KIR on their peripheral NK cells. Recipients lacking the specific HLA ligand for donor KIR could benefit from enhanced antitumor activity after HCT.

The specificity of the dominant inhibitory KIR receptors for its ligand is governed by residues 77 and 80 of HLA-C and by the HLA-Bw4 epitope present on some HLA-B and HLA-A molecules. For HLA-C, ligands are classified into two groups, named C1 and C2. Inhibitory KIR2DL2 and 2DL3 receptors recognize Ser77 and Asn80 present in the following C1 ligands: HLA-Cw1, Cw3 (except Cw*0307, 0310, 0315), Cw7 (except Cw*0707, 0709), Cw8, Cw12 (except Cw*1205,12041/2), Cw13, Cw14 (except Cw*1404), Cw*1507, and Cw16 (except Cw*1602). The KIR2DL1 receptor recognizes Asn at position 77 and Lys at position 80 of the following C2 ligands: HLA-Cw2, Cw*0307, Cw*0315, Cw4, Cw5, Cw6, Cw*0707, Cw*0709, Cw*1205 Cw*12041/2, Cw15 (except Cw*1507), Cw*1602, Cw17, and Cw18. The HLA-Bw4 epitope serves as a ligand for the inhibitory KIR3DL1 receptor. The following HLA-B antigens and alleles are Bw4 positive: B5, B13, B17, B27, B37, B38, B44, B47, B49, B51, B52, B53, B58, B59, B63, B77, B*1513, B*1516, B*1517, B*1523, and B*1524. Based on high-resolution typing of HLA class I alleles of the recipient, the presence or absence of ligands and whether the recipient is C1/C2 heterozygous, C1/C1 homozygous, or C2/C2 homozygous is determined.

The concept of donor NK-mediated killing of recipient antigen-presenting cells was demonstrated in mice and suggested by a study in patients who underwent HLA haplotype-incompatible T-cell–depleted mismatched transplantation for high-risk AML or ALL.[36] These patients received a high $CD34^+$ cell dose and no postgrafting

immunosuppression, a regimen that promotes rapid NK recovery. AML patients who received transplants from KIR ligand–mismatched donors had significantly improved 5-year survival rates compared with patients who received KIR ligand–matched transplants (60% vs. 5%; $P = 0.0005$). Donor KIR ligand mismatching was associated with no graft failure, no acute GVHD, and a 0% 5-year probability of relapse in cases of transplantation for AML. Relapse of ALL was not associated with KIR mismatching, presumably because NK cells do not express adhesion receptors to LFA-1–deficient ALL cells. In contrast, KIR ligand mismatching was an independent risk factor for poor transplantation outcome (15.5% incidence of graft failure, 13.7% incidence of acute GVHD, and 75% 5-year probability of relapse). Patients carrying the diagnosis of ALL were not protected against relapse with use of KIR ligand–mismatched donors (90% in KIR ligand matched vs. 85% in KIR ligand mismatched at 5 years).

Three aspects of KIR biology in transplantation have been explored: ligand, allele, and haplotype.

Ligands

Beginning with the earliest studies, the concept of KIR ligand mismatching and KIR ligand absence have received the most attention and have been reproduced in some (but not all) studies. Extension of the original concepts of KIR ligand mismatch in the haploidentical transplant model to HLA-matched sibling donor and unrelated donor populations has yielded heterogeneous results and may reflect the vastly different conditioning and immunosuppressive regimens that promote T-cell and NK-cell reconstitution early after transplantation. In one study, HLA genotypes were analyzed in a large population of T cell–replete unrelated donor transplants.[37] Lower posttransplant relapse was observed among HLA-mismatched recipients who were homozygous for HLA-Bw6 and HLA-C KIR ligand groups. This association was not observed among HLA-matched recipients. A population of T cell–replete allografts for ALL, AML, MDS, and CML was examined, and three groups were established based on HLA genotypes ligand and 14 KIR genes: (1) HLA class I antigen matched (KIR ligand matched), (2) class I antigen mismatched but KIR ligand matched, and (3) mismatch at both HLA class I and inhibitory KIR-ligand mismatched.[38] The overall survival at 1 year posttransplant for these three groups differed significantly (59%, 49%, and 30%, respectively). The mismatched groups had lower overall survival and event-free survival compared with the matched group. Furthermore, the group with both HLA and KIR mismatching had higher relapse and TRM than the other groups. A detrimental effect was observed for patients who lacked inhibitory KIR receptors. Among HLA-matched cases, those who lacked C1 or C2 HLA ligand had lower overall survival rates compared with patients with either present. Patients who lacked C1 or C2 had higher TRM compared with patients who had all ligands present. Therefore, for T cell–replete unrelated donor HCT, inhibitory KIR ligand mismatching and missing inhibitory KIR ligands confer higher risk to patients.

In a side-by-side comparison of missing ligand and mismatched ligand in patients undergoing haploidentical transplantation for the treatment of myeloid diseases, Ruggeri et al[39] confirmed the protective effect of mismatched ligand and not missing ligand on disease recurrence. In a large analysis of patients transplanted from unrelated donors for the treatment of myeloid malignancies, patients with low-risk diseases (first complete remission of AML, first chronic phase of CML, early stage myelodysplastic syndrome), a beneficial effect of missing ligand on lowered disease recurrence was readily apparent in both HLA-matched and -mismatched transplants.[40] The protective effect was diminished in patients with more advanced disease.

A large analysis by the JMDP sheds further light on the importance of KIR ligand matching.[41] This study included 1790 T cell–replete unrelated donor transplants. Donor–recipient HLA-C disparity was associated with reduced relapse among patients with ALL. HLA-DPB1 mismatches were associated with lower relapse among CML transplants. Mismatching for the KIR2DL ligand in the GVH vector was associated with an increased risk of relapse for ALL. An increased risk of rejection was observed for KIR2DL ligand mismatches in the HVG vector. The risk of acute GVHD was increased with disparity for HLA-A, HLA-B, HLA-C, HLA-DPB1, and KIR ligand mismatching in the GVHD vector. Mismatching for HLA-A, HLA-B, HLA-DQB1, and KIR ligand in the GVH vector increased mortality. In summary, this analysis demonstrated an important role for HLA-C, HLA-DPB1, and KIR ligand mismatching in GVHD vector on posttransplant relapse. As a whole, KIR ligand mismatching had adverse effects on acute GVHD and rejection and had no survival benefit for patients undergoing T cell–replete unrelated HCT.

The concepts of KIR ligand absence and mismatching have each been explored retrospectively in patients receiving reduced intensity conditioning and in cord blood transplantation. In a series of patients conditioned with low-dose total-body irradiation with or without fludarabine before HLA matched transplantation, the most robust indicator of lower posttransplant relapse was high donor NK chimerism, a finding observed chiefly among patients with no missing ligands (C1, C2, Bw4 positive).[42] The transplantation of cord blood units provides a model for investigating the mismatch ligand model caused by the very high frequency of HLA-C disparity between the recipient and cord blood unit(s). Two such studies have been conducted and have drawn different conclusions. Ligand mismatched patients who received myeloablative conditioning had higher TRM chiefly because of higher rates of acute GVHD.[43] In contrast, lower relapse rates and better survival associated with ligand mismatching, particularly for patients with AML, have also been described.[44] These studies highlight the need for continued analysis of large, well-characterized populations.

Alleles and Haplotypes

The KIR family of genes displays allelic and haplotypic polymorphism. KIR genes are organized into two broad groups of haplotypes known as "group A" and "group B" haplotypes. Group A haplotypes encode primarily inhibitory receptors and the activating *KIR2DS4* gene. Group B haplotypes tend to exhibit more diversity, encoding more activating genes, including *KIR2DS1, KIR2DS2, KIR2DS3, KIR2DS5,* and *KIR3DS1*. The clinical relevance of KIR haplotypes has been explored and reveals that the number of activating KIR genes is a determinant of relapse and DFS.[45] In this analysis, patients received myeloablative in vivo antithymocyte globulin T cell–depleted unrelated transplants. The study population was evaluated according to the presence of donor group A haplotypes (inhibitory receptors with one activating KIR2DS4) and donor group B haplotypes (more activating *KIRD KIR2DS1, KIR2DS2, KIR2DS3, KIR2DS5,* and *KIR3DS1*). KIR ligand mismatching was associated with significantly higher TRM, lower overall survival, and lower DFS compared with ligand matching. Transplantation from donors with group A *KIR* haplotypes or donors with lower numbers of activating *KIR* genes was associated with reduced relapse and improved DFS among AML/MDS recipients and to lesser extent among CML patients. No haplotype effects were observed in patients with ALL. This study indicates not only that the HLA ligand is an important factor but also that the composition of donor KIR haplotypes (i.e., group A KIR haplotypes) influences the risk of relapse and improved DFS.

The clinical importance of KIR haplotypes and haplotype gene content is beginning to come into focus.[45-49] Clinical outcome after allogeneic transplantation correlates with number (0, 1, 2) donor B haplotypes and not with A haplotypes nor with recipient haplotypes.[46,48,50,51] However, the mechanisms of the B haplotype–associated protective effect is not known. In a study of 1409 patients transplanted for AML or ALL, donors were genotyped for 15 *KIR* genes to define B/x or AA haplotypes. B haplotypes were further distinguished by their specific gene content. Homozygosity for motifs of the B haplotype was strongly associated with lowered relapse and improved DFS after both HLA-matched and -mismatched

transplantation for the treatment of AML. As the number of B motifs increased, the risk of relapse decreased, demonstrating a biologic effect of gene/haplotype dose.

If the presence of B haplotypes is associated with lowered relapse, is the protective effect conferred by specific genes *(KIRsDS2, 2DL2),* by absence of genes *(2DL3),* or a combination thereof? New information on activating KIRs may shed some light on potential mechanisms. In a retrospective study of 1087 patients transplanted from HLA-matched or -mismatched unrelated donors for AML, CML, MDS, or ALL using primarily T cell–replete BM as grafting source, KIR3DS1 was genotyped in the donor population and the effect of zero, one, or two copies of the gene was analyzed. As the number of donor copies of KIR3DS1 increased from zero to one to two, the risk of grades II to IV acute GVHD, TRM, and mortality decreased, suggesting a biologic dose effect of 3DS1. The results gave impetus to the study of the B3DS1-positive haplotypes in the study population. To test the hypothesis that the observed putative effects of 3DS1 were associated with 3DS1 or from other haplotype-associated genes, the patient population was further defined according to whether donors possessed no B haplotype or any B haplotype. Although GVHD risk was again lower in B haplotype–positive transplants, the haplotype effect was weaker than the 3DS1 effect; furthermore, possible contribution from 2DS2 among B haplotypes was ruled out by virtue of similar GVHD rates associated with haplotype A-positive transplants. Finally, the presence of the HLA-Bw4 epitope was an independent protective factor for GVHD. Taken together, these observations suggest that clinical outcome is defined by a complex interaction of specific donor activating genes, their gene number, and the target ligand. These observations point to the potential usefulness of prospective integration of recipient and donor KIR genotype information into donor selection to fully maximize NK-driven antileukemic effects.

FUTURE DIRECTIONS

The HLA and KIR genetic systems regulate the transplantation barrier. Clinical outcome after unrelated donor transplantation can be achieved with donor matching for the highly polymorphic HLA loci. When HLA disparity cannot be avoided, judicious selection of a donor with the fewest HLA mismatches and avoidance of certain loci may provide patients with the opportunity for lifesaving transplantation. Disease stage remains a strong predictor of overall transplant outcome, and expediency in timing of transplantation for patients with high-risk disease is paramount. New research avenues include identification of novel MHC resident genetic variation that may contribute to risks of GVHD and TRM and the precise role of the KIR systems in preventing transplant complications and disease relapse.

CHAPTER 107

HAPLOIDENTICAL HEMATOPOIETIC CELL TRANSPLANTATION

Bimalangshu R. Dey and Thomas R. Spitzer

PRINCIPLES AND RATIONALE

The complex innate and adaptive human immune systems are well equipped to withstand major antigenic challenges. Transgressing major histocompatibility barriers has been a particularly severe challenge, and the experience of haploidentical hematopoietic cell transplantation (HCT) has underscored the problems of this approach. Our understanding of the basic immunobiology of HCT across major histocompatibility complex (MHC) barriers has increased dramatically over the past 2 to 3 decades; however, the translation of those discoveries into clinical practice has evolved more slowly. The most formidable complications of HCT across human leukocyte antigen (HLA) barriers, namely, graft rejection and graft-versus-host disease (GVHD), have been more effectively prevented and treated with modern pharmacologic interventions and manipulations of the hematopoietic graft[1] (see box on Haploidentical Hematopoietic Cell Transplantation: Why Bother?).

Realization of the potential of allogeneic HCT has one major limitation: the lack of an HLA-matched related donor in the majority of families. The HLA genes are tightly linked and inherited in a genetic unit called a *haplotype*. Haplotypes can be determined by testing for alleles at three loci: HLA-A, HLA-B, and HLA-DR. Every child inherits one haplotype from each parent. Two siblings have a 25% chance of inheriting the same two parental haplotypes and thus of becoming HLA-genotypically identical. There is always an excellent chance of finding a family member who shares with the patient at least one HLA haplotype but differs in the second haplotype. If the donor's different haplotype is by chance phenotypically identical for HLA-A, HLA-B, and HLA-DR to the recipient's, the results of transplantation following HLA-phenotypically matched related donors are comparable to those after HLA-genotypically identical related donors. However, only approximately 30% of patients have an HLA-genotypically or HLA-phenotypically matched related donor. In approximately 60% of cases without a family donor, an HLA-matched unrelated donor can be identified. In reality, in a substantial proportion of situations an unrelated HLA-compatible adult donor cannot be identified in the needed time frame. Related donors matched for one haplotype but mismatched for the alleles of the other haplotype (haploidentical donors) are virtually always readily available.

The successful performance of haploidentical HCT would mean that most patients would have an immediately available donor both for the transplant and potentially for future modulation of the cellular environment by administration of selected donor cell populations. At least in preclinical animal models, a stronger graft-versus-tumor (GVT) effect has been demonstrated when MHC barriers are crossed.[2] A primary reason for treatment failure after HCT for advanced hematologic malignancies, particularly with use of reduced-intensity conditioning, is recurrent malignancy.[3-5] One way to address the risk for relapse would be to capture the potentially more potent GVT effect of a haploidentical transplant. Finally, the lessons of haploidentical HCT will be important for strategies to induce donor-specific tolerance through mixed lymphohemapoietic chimerism.[6,7]

COMPLICATIONS OF HAPLOIDENTICAL HEMATOPOIETIC CELL TRANSPLANTATION

Although the theoretic rationale for haploidentical HCT is clear, the application of this strategy has been limited by three major complications: GVHD, graft rejection, and prolonged immunodeficiency. These problems are discussed as a prelude to the historical clinical experience of haploidentical HCT and the attempts that have been made to overcome these complications.

Graft-Versus-Host Disease

Not surprisingly, the risk for acute (and perhaps chronic) GVHD is substantially higher after T cell–replete haploidentical HCT than HLA-matched related donor transplantation.[8-10] The frequency and severity of a "hyperacute GVHD" syndrome with pharmacologic prophylaxis was well demonstrated by Powles et al[8] in an early experience with T cell–replete haploidentical bone marrow transplantation (BMT) for advanced acute leukemia. Powles et al reported 35 patients with advanced acute myeloid leukemia (AML) or acute lymphoblastic leukemia (ALL) who received one to three HLA antigen–mismatched related BMT following cyclophosphamide/total body irradiation (TBI) or cyclophosphamide/melphalan conditioning and cyclosporine with or without methotrexate GVHD prophylaxis. Twelve of these patients died of a syndrome consisting of pulmonary edema, seizures, intravascular hemolysis, and/or acute renal failure. Ten patients had primary graft failure requiring a second transplant from the same donor. This life-threatening syndrome probably reflects an inflammatory cytokine cascade associated with a potent graft-versus-host alloresponse (or, in some cases, possibly graft rejection) and illustrates the potentially catastrophic consequences of crossing HLA barriers with pharmacologic GVHD prophylaxis alone.

Beatty et al[9] at the Fred Hutchinson Cancer Research Center also showed in an early retrospective analysis of transplant outcomes that the incidence of acute GVHD was significantly higher after one to three HLA antigen–mismatched BMT compared to HLA-genotypically identical sibling donor transplants. Despite a higher incidence of GVHD, however, overall survival was not significantly different following HLA-matched and single antigen–mismatched donor BMT, likely due to a stronger GVT effect of single antigen–mismatched BMT balancing the harmful effects of acute GVHD. Although the number of patients who received a two or three HLA antigen–mismatched transplant was too small to reach meaningful conclusions, the survival of those patients was poor and indicated that the mortality risk of transplants was unacceptably high in donor-recipient pairs with more than a single-antigen mismatch.

Use of ex vivo T-cell depletion of the haploidentical hematopoietic graft can result in a substantially lower incidence of GVHD, albeit in some experiences with a greater risk for engraftment failure.[11] With "megadose" peripheral blood stem cells (PBSCs) obtained by stimulation of the donor with high-dose granulocyte colony-stimulating factor (G-CSF) and vigorous ex vivo T-cell depletion, the probability

Haploidentical Hematopoietic Cell Transplantation: Why Bother?

Haploidentical hematopoietic cell transplantation (HCT) involves related donor-recipient combinations sharing one haplotype who are mismatched for one to three human leukocyte antigens (HLA) on the other haplotype

- Only 30% of patients have an HLA genotypically or phenotypically matched related donor
- Successful haploidentical HCT would mean that most patients would have an immediately available donor
- A more potent graft-versus-tumor (GVT) effect may occur following histoincompatible HCT

Myeloablative Haploidentical HCT: Survival Outcomes—Conclusions in 1985

- Equivalent following HLA-matched and single HLA antigen–mismatched related HCT
- Inferior following two to three HLA antigen–mismatched HCT

Myeloablative Haploidentical HCT: Conclusions in 1997

- For favorable-risk hematologic malignancies
 Haploidentical HCT is associated with inferior survival outcomes
- For intermediate- to high-risk hematologic malignancies
 Single HLA antigen–mismatched related transplant equals matched unrelated-donor transplant
- For intermediate- to high-risk hematologic malignancies
 Two HLA antigen–mismatched related transplant equals single HLA antigen–mismatched unrelated donor transplant

Haploidentical HCT: Conclusions in 2011

Haploidentical HCT is feasible in selected circumstances in which matched donors are unavailable. However, the following problems remain:

- It is unclear whether a stronger graft-versus-leukemia effect occurs
- Graft-versus-host disease (GVHD) and graft rejection are problematic, although becoming more manageable with vigorous T-cell depletion (TCD) and high stem cell dose
- Immune reconstitution, particularly following TCD, is poor

Nonmyeloablative Haploidentical HCT: Rationale

- Reduced early transplant-related mortality
- More candidates for HCT by virtue of age or comorbidity
- Mixed chimeric platform to prevent GVHD and optimize a GVT effect via donor lymphocyte infusion

Nonmyeloablative Haploidentical HCT: Conclusions

- Engraftment occurs in the majority of cases
- GVHD, prolonged immunodeficiency, and disease relapse remain challenging
- Mixed chimerism is achievable and may serve as a platform for adoptive cellular therapy
- Sustained remissions following donor graft rejection are seen and suggest an alternative antitumor mechanism
- Mixed chimerism can be used as a platform for achieving donor-specific solid organ tolerance

of sustained engraftment after haploidentical transplant was high (100/101 patients in one series),[1] and the probability of acute GVHD was very low (8%) in that same series. However, the complications of severe opportunistic infection and disease relapse, reflecting inadequate immune reconstitution, persist with this approach.[12,13]

Graft Rejection

A strong association between the degree of HLA incompatibility and graft failure was well demonstrated by Anasetti et al[14] in an analysis of 269 myeloablative BMTs for leukemia or lymphoma. The overall rate of graft failure for transplants from haploidentical donors was 12.3% compared to 2.0% for transplants from genotypically identical sibling donors. The graft failure rate also correlated with the degree of histocompatibility with 9% and 21% graft failure rates for transplants from single-locus mismatched and two-loci mismatched donors, respectively. Incompatibility at both the B and D loci and a positive crossmatch for antidonor lymphocytotoxic antibody independently predicted graft failure.

With T-cell depletion of bone marrow grafts, graft failure rates after haploidentical HCT have been very high.[15] The problem of graft failure has been overcome in large part by the use of very-high-dose G-CSF–mobilized PBSCs, as discussed in Principles and Rationale.[1] A "veto" function of $CD34^+$ cells and selected $CD8^+$ cells likely has contributed to the high rate of sustained engraftment with this strategy.[16,17]

Nonmyeloablative haploidentical HCT approaches have been explored more recently. Higher rates of graft failure have been observed with T cell–replete bone marrow versus T cell–depleted G-CSF–mobilized PBSCs.[18,19] Posttransplant high-dose cyclophosphamide also has been used to deplete alloreactive (in both the GVH and host-versus-graft directions) T cells with a high rate of sustained engraftment following nonmyeloablative haploidentical BMT.[20]

Prolonged Immunodeficiency

The well-known serious consequences of haploidentical HCT, including relapse and delayed immune recovery with resultant risk for fatal infectious complications, are complicated by the rigorous T-cell depletion that is necessary to prevent fatal GVHD. Delayed immune recovery after T cell–depleted haploidentical HCT has been associated with a very high risk for bacterial, fungal, viral, and other opportunistic infections.[13,21,22] With refinements in transplant strategy, including the use of "megadose" $CD34^+$ cells, the rate of donor engraftment has improved with a very low incidence of GVHD, but infectious complications have remained a substantial problem.[23] In this important study, the mortality from causes other than leukemic relapse was 40%. The high incidence of infectious complications, which occurred despite the use of antibacterial, antifungal, and antiviral prophylaxis, resulted in 59% of all nonleukemic deaths. Of note, $CD4^+$ T-cell counts were below 200/μL for as long as 16 months. Immune recovery was faster in patients who received 10 times as many T cells, but that resulted in an increased incidence of GVHD.[24]

Delayed immune recovery results from the degree of HLA disparity, the low numbers of T cells infused, the use of T cell–depleting serotherapy (e.g., antithymocyte globulin [ATG]), the intensity of the conditioning regimen, and impaired thymic function.[25,26] Development of a fully functional immune system requires recovery of both innate and adaptive immune responses. Whereas the innate system, represented by natural killer (NK) cells, neutrophils, dendritic cells, monocytes, and macrophages, is restored relatively rapidly, the recovery of the adaptive system, represented by a broad functional T- and B-cell repertoire, is markedly delayed following T cell–depleted haploidentical HCT. T-cell reconstitution occurs through two main pathways: early reconstitution via a thymic-independent pathway known as *homeostatic peripheral expansion,* which involves expansion of mature T cells that survive the conditioning and/or are retained within the allograft, and late reconstitution via a thymic-dependent pathway. Although a broad T-cell repertoire presumably resulting from donor precursor cells emigrating from the thymus (i.e., via thymopoiesis) provides optimal T-cell reconstitution, effective immune reconstitution can occur relatively early through homeostatic peripheral expansion alone conferring protection against disease progression and infectious pathogens. However, this recovery is effectively eliminated by T-cell depletion in the haploidentical HCT setting. Impaired thymic function as a result of toxicity of the conditioning regimen or GVHD further contributes to delayed immune recovery.[26-28] Lamb et al[22] demonstrated NK cell recovery as early as 1

month posttransplant, with B- and T-cell recovery at 6 months and more than 2 years, respectively, in patients who received T cell–depleted haploidentical HCT.

HISTORICAL CLINICAL EXPERIENCE OF HAPLOIDENTICAL HEMATOPOIETIC CELL TRANSPLANTATION

The first reported successful allogeneic transplants were performed in children with primary immunodeficiency syndromes who received HLA-matched sibling donor bone marrow.[29,30] Based on this initial encouraging experience, T cell–depleted parental donor haploidentical BMT was attempted. This strategy subsequently was shown to be successful in a number of primary immunodeficiency disorders, including severe combined immunodeficiency disease and Wiskott-Aldrich syndrome.[31,32] Despite the early successes of HLA-matched BMT and the realization that only sustained lymphoid chimerism was necessary for functional cure of these diseases, it was quickly learned that more aggressive conditioning was required to overcome HLA barriers in the haploidentical BMT setting.[33,34]

The early clinical experience with myeloablative T cell–replete BMT with pharmacologic GVHD prophylaxis for treatment of hematologic malignancies was remarkable for a significantly higher incidence of GVHD compared to HLA-matched related donor transplants[9] and a high incidence of early and severe ("hyperacute") GVHD.[8] The comparable survival of patients in the Beatty report who received an HLA-matched versus a single antigen–mismatched donor BMT despite a higher incidence of acute GVHD in the latter patient population was believed to result from a stronger GVT effect of HLA single antigen–mismatched BMT balancing the harmful effects of acute GVHD. Too few patients received a two or three HLA antigen–mismatched transplant to reach meaningful conclusions, but the poor outcomes of those patients suggested that the mortality risk of transplants involving donors who were more than a single-antigen mismatch with their recipient was unacceptably high.

An International Bone Marrow Transplant Registry analysis of transplant outcomes following HLA-matched and HLA-mismatched related and unrelated donor BMT for AML, ALL, and chronic myeloid leukemia (CML) added to our understanding of transplant outcomes according to degree of histocompatibility. In this analysis, transplant-related mortality was significantly higher after a one or two HLA antigen–mismatched related or matched or single antigen–mismatched unrelated donor BMT than after HLA-matched sibling BMT.[10] The large number of patients also permitted an analysis of outcomes according to leukemia status at the time of transplant. Among patients with early leukemia (AML or ALL in first complete remission or CML in chronic phase), transplants from non–HLA-matched related donors were associated with a higher risk for transplant-related mortality than were matched donor transplants. The risk for treatment failure also was higher following alternative donor BMT. For patients with more advanced leukemia, treatment failure risk was similar for HLA-matched donor transplants and single antigen–mismatched related donor transplants and lower than the treatment failure risk following matched unrelated donor and two HLA antigen–mismatched related donor BMT. Although this study demonstrated the importance of leukemia status and the impact of HLA matching on treatment failure risk and survival outcomes, the analysis was limited by the heterogeneous groups of patients (including, for example, both T cell–depleted and T cell–replete transplants) and the exclusive use of serologic methods of HLA typing (thus underestimating the HLA disparity that now can be identified by molecular methods).

Drobyski et al[35] compared the transplant outcomes of 139 patients with hematologic malignancies who underwent T cell–depleted BMT from HLA-matched unrelated, single antigen–mismatched unrelated, and related haploidentical donors. No significant differences in rates of engraftment or cumulative incidences of acute or chronic GVHD were observed among the three groups. Surprisingly, a higher 2-year cumulative relapse probability was observed after haploidentical BMT, and transplant-related mortality risk was higher in both the haploidentical and single antigen–mismatched unrelated donor groups. Overall survival was significantly higher in the HLA-matched unrelated donor group.[35]

RECENT HAPLOIDENTICAL HEMATOPOIETIC CELL TRANSPLANTATION APPROACHES

In an effort to overcome the complications of haploidentical HCT and to improve disease-free and overall survival, a number of strategies have been developed (Tables 107-1 and 107-2). Both myeloablative and nonmyeloablative (reduced-intensity) conditioning regimens have been evaluated. The most successful approaches have been those that address and modulate the T-cell content (or function) of the graft and provide sufficient immunosuppression to allow for sustained engraftment.

Myeloablative Haploidentical Hematopoietic Cell Transplantation: Ex Vivo T-Cell Depletion

An abundant preclinical experience[36] and an early randomized clinical trial in patients undergoing HLA-matched BMT[37] showed that GVHD could be effectively prevented following ex vivo T-cell depletion of the graft. However, increased rates of graft failure and disease recurrence showed important limitations of this strategy.

Mehta et al[38] in a series of haploidentical BMT clinical trials evaluated TBI-based myeloablative conditioning with partial (1 to 1.5 log reduction) T-cell depletion of the allograft and posttransplant cyclosporine-based pharmacoprophylaxis. Ex vivo T-cell depletion was accomplished with either a T10B9 (anti-$\alpha\beta$ T-cell receptor) monoclonal antibody or OKT3 (anti-CD3) monoclonal antibody. Sustained engraftment occurred in more than 90% of their transplants, which was attributable to an intensified conditioning regimen and the incomplete T-cell depletion. The incidence of acute GVHD was low in one report, and an encouraging long-term survival probability of 20% in patients with advanced hematologic malignancy was observed.

Using high numbers of PBSCs to address the problem of graft loss and more vigorous T-cell depletion to prevent GVHD, Aversa et al[23] demonstrated a very low incidence of GVHD and impressive event-free and overall survival probabilities following myeloablative haploidentical HCT in patients with acute leukemia. Conditioning therapy consisted of TBI, thiotepa, fludarabine, and ATG. Ex vivo T-cell depletion was performed using $CD34^+$ cell selection (most recently with a Miltenyi CD34 cell selection device). With "megadose" PBSC containing a median of 13.6×10^6 (range, 5.1 to 29.7×10^6) $CD34^+$ cells/kg, sustained engraftment was reliably achieved with minimal acute or chronic GVHD. In a published experience, 104 patients with AML (n = 67) or ALL (n = 37) received a haploidentical T cell–depleted HCT using this regimen. Engraftment ultimately was achieved in 100 of 101 evaluable patients. Eight patients had grade II or higher acute GVHD, whereas 5 of 70 patients developed chronic GVHD. A 38% nonrelapse mortality risk, predominantly due to opportunistic infection, occurred. Killer immunoglobulin-like receptor (KIR) ligand mismatching in the GVH direction was shown to be associated with strikingly less relapse following transplantation for AML.[39] No difference in relapse probability was observed for ALL, according to KIR ligand compatibility.

Several pediatric experiences have demonstrated high rates of sustained engraftment and a low incidence of GVHD following vigorously T cell–depleted HCT for nonmalignant hematologic disorders and hematologic malignancy.[40-42] Using positive selection of stem cells with $CD34^+$- or $CD133^-$-coated magnetic microbeads or, more recently, depletion of T and B cells using $CD3^-$- and $CD19^-$-coated microbeads, Lang et al[40,41] reported high probabilities of primary engraftment in their patients (highest in the CD3/CD19 group at 91%). Of 63 patients with long-term follow-up transplanted with $CD34^+$- or $CD133^-$-selected cells, 83% achieved stable primary engraftment (which increased to 98% after re-transplant). Grade II to IV acute GVHD occurred in less than 10% of

patients. Disease-free and overall survival probabilities for patients with nonmalignant disease and hematologic malignancy (non-Hodgkin lymphoma or ALL in complete remission) were 60% and 48%, respectively. A less than 10% incidence of fatal viral infections in recently transplanted patients was observed, suggesting favorable immune reconstitution in this population of pediatric patients.

Marks et al[43] treated 34 children having acute leukemia and other hematologic malignancies with TBI/cyclophosphamide and alemtuzumab or ATG followed by T cell–depleted (either by $CD34^+$ cell selection or ex vivo treatment with alemtuzumab) megadose PBSC transplantation. Cyclosporine as sole GVHD prophylaxis was used only for children who did not receive $CD34^+$ cell–selected grafts. Twenty-four patients (71%) died of relapse or infection. Actuarial overall survival at 2 years was 26%. Of the nine patients with refractory AML, there were no long-term survivors.

The experience with myeloablative ex vivo T cell–depleted (by $CD34^+$ cell selection) "megadose" PBSC transplantation for hematologic malignancy has not been universally favorable. High early nonrelapse mortality rates due to impaired immune reconstitution (resulting in a high incidence of opportunistic infections or recurrent malignancy) have been reported with this approach. Cavazzana-Calvo et al[13] reported a mortality rate of 93% (26 of 28 patients), mostly due to infection or relapse, following ATG-based myeloablative conditioning and high-dose $CD34^+$ cell–selected PBSC transplantation. In a Canadian multicenter trial using myeloablative conditioning and $CD34^+$ cell–selected PBSC grafts, 10 (91%) of 11 patients died of infection or recurrent leukemia.[12] The reasons for the inferior survival outcomes in these trials are unclear but may reflect patient selection (i.e., transplantation of patients with more advanced disease) or modifications of the treatment regimen.

Ex Vivo T-Cell Anergization

Given the impaired reconstitution following nonselective T cell–depleted HCT and based on experiments showing ex vivo induction of alloantigen-specific anergy by coculturing of host and donor bone marrow mononuclear cells in the presence of cytotoxic T-lymphocyte antigen 4 immunoglobulin (CTLA4Ig), Guinan et al[44] conducted a trial of ex vivo anergized haploidentical BMT in an attempt to induce alloantigen-specific tolerance. Anergy was demonstrated by measuring precursor T-cell frequencies before and after ex vivo treatment of the marrow graft. A multiple log decrease in antirecipient precursor helper T-cell frequency was demonstrated after ex vivo anergization. Anti–third party precursor helper T-cell frequency was not significantly changed by ex vivo treatment of the graft. Twelve patients with advanced hematologic malignancy received TBI-based myeloablative conditioning and ex vivo anergized BMT. Three patients developed acute gastrointestinal GVHD. Five of 12 patients were alive and disease free from 4.5 to 29 months following transplant.

Table 107-2 Non–Ex Vivo T Cell–Depleted Haploidentical Stem Cell Transplantation

		Conditioning	GVHD (%)			
Center	**Disease**	***GVHD prophylaxis***	***Acute***	***Chronic***	**NRM**	**EFS or DFS/OS**
Royal Marsden[8] (N = 35)	AML/ALL	TBI/CY or TBI/MEL CYA ± MTX	80%	18%	34%	NS/31% at 6 mo-3 yr

Myeloablative Haploidentical Hematopoietic Cell Transplantation With In Vivo T-Cell Depletion

Because of the very high incidence of GVHD and transplant-related mortality following non–T cell–depleted haploidentical HCT, most of the recent efforts in this field have focused on ex vivo T-cell or T-cell subset depletion. Recently, however, several groups have reported impressive, acceptably low transplant-related mortality and favorable survival probabilities following non–T cell–depleted PBSC transplantation. Common to these strategies, however, has been the use of polyclonal ATG for in vivo T-cell depletion.

Lu et al[45] treated 135 patients having a variety of hematologic malignancies with busulfan, cytarabine, cyclophosphamide, rabbit ATG (on days −5 through −2), and non–ex vivo T cell–depleted bone marrow and/or PBSC transplantation. GVHD prophylaxis consisted of mycophenolate mofetil, cyclosporine, and methotrexate. All patients had full donor chimerism at day 30 posttransplant. The cumulative incidence of grades II to IV acute GVHD was 40%, and the 2-year incidence of transplant-related mortality was 22%. The probability of relapse at 2 years was 18%. Infectious complications included cytomegalovirus virus (CMV) interstitial pneumonitis and hemorrhagic cystitis in 17% and 35% of patients, respectively. Two-year leukemia-free and overall survival probabilities were 64% and 71%, respectively.

Ogawa et al[46] used reduced-intensity conditioning (busulfan, fludarabine, and rabbit ATG) as preparation for two to three HLA antigen–mismatched non–ex vivo T cell–depleted PBSC transplantation in 26 patients with high-risk hematologic malignancies. GVHD prophylaxis consisted of tacrolimus and corticosteroids. Serum-soluble interleukin-2 receptor (sIL-2R) levels were followed, and tapering of corticosteroids was based partly on the results of these assays. Twenty-five of the 26 patients achieved full donor chimerism. Five patients developed grade II acute GVHD, and 5 of 20 evaluable patients developed chronic GVHD. Transplant-related mortality was 15% (4 of 26 patients). $CD4^+$ cell recovery was slow, with a median count greater than 100/μL at 9 months. Fifteen (58%) of the 26 patients were alive and in complete remission at a median of 664 days posttransplant.

The surprisingly low incidence of GVHD in these series compared to historical experiences of non–ex vivo T cell–depleted HCT likely reflects the use of ATG for in vivo T-cell depletion, improved GVHD prophylaxis strategies, and better prevention and treatment of opportunistic infections. The importance of genetic factors (i.e., heterogeneity of the population) and other factors, such as use of donors mismatched for noninherited maternal antigens, remains to be determined in future clinical trials of non–ex vivo T cell–depleted haploidentical transplant.

Nonmyeloablative Conditioning for Haploidentical Hematopoietic Cell Transplantation

Nonmyeloablative (reduced-intensity) conditioning for HCT is associated with significantly less transplant-related morbidity and mortality than is myeloablative conditioning, thus permitting the transplantation of older patients and patients with significant pretransplant comorbidity.[3-5,47] A variety of postulated mechanisms, including less proinflammatory cytokine production and preservation of host "regulatory" cellular elements observed after nonmyeloablative transplants, may account for less clinical evidence of GVHD.[48] A potent GVT effect may be achieved, following either spontaneous or donor lymphocyte infusion (DLI)-induced conversion of mixed to full donor lymphohematopoietic chimerism.[4,49]

NONMYELOABLATIVE HAPLOIDENTICAL HEMATOPOIETIC CELL TRANSPLANTATION STRATEGIES USING IN VIVO T-CELL DEPLETION

Pelot et al[49] showed in murine MHC-mismatched transplant models that mixed lymphohematopoietic chimerism can be reliably induced following nonmyeloablative conditioning, in vivo T-cell depletion with anti-CD4 and anti-CD8 monoclonal antibodies, and thymic irradiation. Remarkably, these mixed chimeric mice are resistant to induction of GVHD following delayed DLI, despite a potent lymphohematopoietic GVH response, which converts their mixed chimerism to full donor hematopoiesis. A more potent GVT effect has been demonstrated in mixed chimeric mice that convert to full donor chimerism after DLI, compared to full donor chimeras given DLI (with the enhanced antitumor effect shown to result from the preservation of host professional antigen-presenting cells).[50,51]

Based on these murine models, a series of haploidentical nonmyeloablative HCT clinical trials have been conducted at the Massachusetts General Hospital. The initial trials involved cyclophosphamide, equine ATG for in vivo T-cell depletion, and pretransplant thymic irradiation.[52] Cyclosporine was given as GVHD prophylaxis and was tapered and discontinued by 5 weeks posttransplant in the absence of GVHD. DLIs were given to patients with mixed chimerism and without GVHD in an attempt to maximize the GVT effect. Because of a high incidence of severe acute GVHD in the initial group of patients, the monoclonal anti-CD2 antibody MEDI-507 was substituted for ATG in an effort to effect a more complete T-cell depletion.[18] A series of protocol changes have since been made, including the use of ex vivo T cell–depleted G-CSF–mobilized PBSCs (rather than bone marrow), changes in the dose and schedule of MEDI-507, and the addition of fludarabine to address the problems of GVHD and graft failure. Mixed "split-lineage" lymphohematopoietic chimerism has been achieved in all of the patients treated with ex vivo T cell–depleted PBSCs, with an early predominance of donor granulocyte chimerism and a much lower percentage of donor T-cell chimerism. In the majority of these patients, mixed chimerism in all lineages has converted to full or nearly full donor chimerism, either with tapering of immunosuppression or following DLI. Although GVHD has occurred in the majority of patients following conversion to full donor chimerism, it has been manageable in most cases. Striking antitumor responses in selected patients with chemorefractory aggressive lymphomas also have been achieved.

An unexpected observation in these clinical trials and HLA-matched nonmyeloablative HCT trials at the Massachusetts General Hospital was that durable antitumor responses in some patients with chemorefractory hematologic malignancies occurred despite loss of the hematopoietic graft.[53] Nine (41%) of 22 patients who received an HLA-matched or haploidentical nonmyeloablative HCT achieved a response after loss of their graft. Six patients were alive from 2.5 to 5.5 years posttransplant; four of these patients were in a sustained complete remission. The observation of ongoing tumor regression following serial DLI in a patient who lost his graft, accompanied by "spikes" in circulating host $CD8^+$ T cells, raised the intriguing possibility that a host-specific antitumor response was induced. In an effort to elucidate the mechanism of these antitumor responses, Rubio et al[54,55] established a murine nonmyeloablative transplant model in which recipient lymphocyte infusions were administered in order to cause rejection of the graft, followed by tumor challenge with host strain-specific malignant cells. A survival benefit was observed in the mice that developed mixed chimerism followed by recipient lymphocyte infusion–induced graft rejection compared to mice that received conditioning only, conditioning and transplant, or conditioning and recipient lymphocyte infusions alone. The antitumor response has been shown to be mediated by recipient lymphocyte infusion–derived interferon-γ–producing $CD8^+$ cells and recipient $CD4^+$ cells.

Rizzieri et al[56] at Duke University Medical Center have used anti-CD52 monoclonal antibody therapy (alemtuzumab) for both ex vivo and in vivo T-cell depletion in a clinical trial of haploidentical nonmyeloablative HCT for hematologic malignancies and selected solid tumors. Conditioning consisted of fludarabine, cyclophosphamide, and alemtuzumab, followed by infusion of alemtuzumab-treated PBSCs. GVHD prophylaxis consisted of mycophenolate mofetil with or without cyclosporine. DLIs were given to patients with persistent disease. Of 49 patients, 8 (16%) developed grade II to IV acute GVHD, and 7 (14%) developed chronic GVHD. Three patients (6%) experienced primary graft failure, and 4 (8%) had secondary graft failure. The complete remission rate was 75%; relapse-free and overall survival probabilities at 1 year were 43% and 31%, respectively.

Nonmyeloablative Haploidentical Hematopoietic Cell Transplantation With Posttransplant High-Dose Cyclophosphamide

Based on canine experiments in which high-dose posttransplant cyclophosphamide was effective in depleting alloreactive T cells in both the GVH and host-versus-graft directions, investigators at Johns Hopkins have performed a series of studies to determine the minimal conditioning needed to achieve stable engraftment after one to three HLA antigen–mismatched BMT. Sixty-eight patients with advanced hematologic malignancies received cyclophosphamide 50 mg/kg intravenously on day 3 (n = 28) or on days 3 and 4 (n = 40) after transplantation.[20] Graft failure occurred in 9 of 66 (14%) evaluable patients and was fatal in 1. The cumulative incidences of grades II to IV and grades III to IV acute GVHD by day 200 were 34% and 6%, respectively. Actuarial overall survival and event-free survival at 2 years after transplantation were 36% and 26%, respectively. More recently this approach has been evaluated in a multicenter study using a conditioning regimen of cyclophosphamide, fludarabine, and 200 cGy of total body irradiation. The 1-year probabilities of overall and progression-free survival in 50 patients after haploidentical marrow transplantation were 62% and 48%, respectively, confirming the exportability of this approach.[57]

Selective Allodepletion

Nonselective depletion of T cells from the allograft before transplantation effectively prevents severe acute GVHD but invariably predisposes the recipient to loss of the graft, disease relapse, and an increased incidence of infectious complications. Unmanipulated T-cell add-backs likely will not be effective in preventing these problems without causing GVHD because the frequency of alloreactive T cells in the peripheral blood is far greater than that of either specific antiviral or antileukemic T cells. One approach to overcoming these adverse outcomes is to selectively deplete the graft of the GVHD-causing alloreactive T cells identified by upregulation of activation markers while conserving cells mediating GVT and antimicrobial immune responses. Several methods of selective removal of alloreactive T cells have been reported that rely on ex vivo stimulation of donor T cells by recipient peripheral blood mononuclear cells in a unidirectional mixed lymphocyte reaction culture. Host-reactive donor T cells can be identified by their expression of activation markers (CD25, CD69, CD71), proliferative potential, or preferential retention of photoactive dyes. They subsequently can be targeted for depletion using a variety of methods, including an immunotoxin,[58,59] immunomagnetic bead separation,[60-63] fluorescence-activated cell sorting,[64,65] photodynamic purging,[66,67] or Fas–Fas ligand–mediated apoptosis.[68] These selective allodepletion methods have yielded 70% to 95% reductions in alloreactivity in vitro, with retention of immune responses against third-party and infectious organisms. Several methods even allow retained alloreactivity against leukemia cells.[66,69-71] Although this promising approach has been shown to be feasible in clinical trials,[72,73] several concerns have been raised, including contamination of recipient peripheral blood mononuclear cells by leukemic cells, loss of antileukemic activity, and induction of clinically significant GVHD. In a clinical trial, Amrolia et al[74] used different cell doses for allodepleted (via immunotoxin) T-cell add-back. At a dose level of 10^5 $CD3^+$ cells/kg, patients exhibited

significantly more rapid recovery of T cells at 3 to 5 months after haploidentical HCT than did patients who received 10^4 $CD3^+$ cells/kg. The incidence of GVHD was very low, and the median time to reach a $CD4^+$ cell count greater than 300/μL was 4 months in patients at a dose of 10^5 $CD3^+$ cells/kg compared with more than 6 months in patients at a dose of 10^4 $CD3^+$ cells/kg and 8 months in the series by Eyrich et al[75] without allodepleted T-cell add-back. A similar improvement in immune reconstitution without GVHD has been demonstrated by another group that used photodynamic therapy for selective depletion of alloreactive T cells.[76] Bear in mind that however small the alloreactive T-cell subset of the total T-cell population (<0.1% in the HLA-matched sibling setting; 1% to 5% in the HLA-mismatched setting), their complete elimination may be difficult, and doses of unmanipulated T cells as low as 3 to 10^3 cells/kg can be associated with severe GVHD following haploidentical HCT. Mielke et al[77] at the National Institutes of Health demonstrated that selective depletion of alloreactive T cells preserves a $CD25^-CD4^+Foxp3^+$ fraction of T cells that is capable of undergoing marked expansion posttransplant to regulatory T cells (Tregs), which can provide protection against GVHD.

CHOICE OF DONORS FOR HAPLOIDENTICAL HEMATOPOIETIC CELL TRANSPLANTATION: SPECIAL CONSIDERATIONS

Exploiting KIR Ligand Mismatching in the Graft-Versus-Host Direction

NK-cell alloreactivity in the GVH or host-versus-graft direction can be a powerful means of optimizing the efficacy and safety of haploidentical HCT. NK cells are a unique $CD56^+CD3^-$ cell population composing approximately 10% of peripheral blood lymphocytes[78,79] and are involved in innate antiviral and antitumor immune responses[80-83] (see Chapter 20). They constitute a heterogeneous population of different cell subsets with distinct phenotypic and functional characteristics. The majority (90%) are highly cytotoxic $CD56^{dim}$ cells likely functioning as efficient effector cells, whereas a minority (10%) are immunoregulatory $CD56^{bright}$ cells producing cytokines.[84,85] Following HCT, including haploidentical transplant with selected $CD34^+$ cells, NK cells recover as early as 2 to 3 weeks posttransplant by rapid differentiation from engrafted $CD34^+$ cells.[14,22,86]

The "missing self" recognition concept was hypothesized 2 decades ago by Klas Karre. He suggested that, unlike T and B cells, NK cells are activated by the absence of self-MHC class I molecules on the surface of target cells.[87-90] Expression of self-MHC molecules on target cells delivers an inhibitory signal to NK cells via inhibitory KIRs. In the absence of this inhibitory signal, NK-cell alloreactivity, manifested by NK cell–mediated target cell lysis, proceeds by default. When NK cell–inhibitory receptors are engaged by KIR-specific epitopes, killing is inhibited, whereas killing of target cells occurs when NK cell–inhibitory receptors are not engaged, because of either absence of MHC class I or MHC mismatch. Because virally infected cells and tumor cells downregulate MHC expression to escape adaptive immune surveillance, the ability of NK cells to identify "missing self" is critical in (innate) immune response against viruses and tumor cells.[91,92] Essentially all NK cells express at least one inhibitory receptor that is specific for a self-MHC class I epitope, thereby preventing autoreactivity.[93] NK cells also have activating receptors, most notably NKG2D and NKp46, which can trigger NK-cell alloreactivity when they are engaged by appropriate antigens on virally infected cells and tumor cells.[94-97] Although inhibitory signals are believed to dominate over activating signals, NK-cell activity is regulated by quantitative differences in cumulative inhibitory and activating signals transmitted via KIRs. Therefore the presence or absence of the respective ligands on recipient cells determines if NK cells will be primed to be alloreactive and kill the targets.[79,98]

By selecting haploidentical stem cell donors whose NK cells are not fully inhibited by recipient MHC class I ligands, that is, there is a KIR ligand mismatch in the GVH direction, the graft NK-cell alloreactivity may be used to optimize a GVT effect. As discussed in Myeloablative Haploidentical HCT: Ex Vivo T-Cell Depletion, Ruggeri et al[39,99] found that HLA (KIR ligand) mismatching in the GVH direction following T cell–depleted haploidentical HCT is associated with strong NK-cell alloreactivity leading to (1) a dramatically reduced relapse in patients with AML, (2) a lower rate of graft rejection, and (3) a reduction in GVHD. As supported by their animal studies, the reduction in GVHD is due to donor NK-mediated depletion of host antigen-presenting cells that are crucial in priming alloreactive donor T cells and hence in the pathogenesis of GVHD, and donor NK cells that attack host hematopoietic cells and spare epithelial GVHD target tissues.[39,99,100] The lower rates of graft rejection were shown to be due to donor NK–mediated lysis of host residual T cells, thereby preventing them from rejecting the graft. Furthermore, in their murine transplant model they showed that pretransplant transfer of NK cells into mice improved engraftment after transplantation, allowing durable full donor chimerism following reduced-intensity conditioning. This NK-cell conditioning prevented GVHD well enough to allow for safe infusion of otherwise lethal doses of allogeneic T cells, which were given to facilitate immune reconstitution.

Fetomaternal Microchimerism

Several transplant centers have developed haploidentical HCT strategies based on the principle of tolerance induction as a result of in utero exposure to maternal antigens and the development of long-lasting fetomaternal microchimerism.[101] A large International Bone Marrow Transplant Registry analysis by van Rood et al[102] showed that the incidence of grade II or higher acute GVHD following non–T cell–depleted haploidentical HCT was related to haplotype inheritance. Transplants from a noninherited maternal antigen–mismatched sibling were associated with significantly less acute GVHD. Moreover, transplant-related mortality was significantly higher in transplants from a maternal or a paternal donor. Several Japanese transplant centers have performed non–T cell–depleted transplants following either myeloablative or nonmyeloablative conditioning from microchimeric noninherited maternal antigen–mismatched donors.[103-106] Although the overall incidence of grade II or higher acute GVHD incidence was high (56% of 34 evaluable patients) in one series, a significantly lower risk for acute GVHD was observed in patients who received a transplant from a donor who was noninherited maternal antigen mismatched in the GVH direction.

IMMUNE RECONSTITUTION FOLLOWING HAPLOIDENTICAL HEMATOPOIETIC CELL TRANSPLANTATION

Transfer of a functional lymphohematopoietic system from donor to recipient in a timely fashion determines in large part the eventual success of HCT. Given the problem of delayed immune reconstitution with resultant risk for infectious complications and disease relapse following haploidentical transplantation, particularly after ex vivo T cell–depleted HCT, new strategies are required to limit the severity and duration of this immunodeficiency. Both adoptive cellular therapy approaches and strategies using soluble factors are being investigated (see box on Haploidentical Hematopoietic Cell Transplantation: Ongoing Novel Efforts to Improve Transplant Outcomes).

Immunotherapy involving both cellular and soluble factors can be guided by two distinct concepts: (1) enhancement of general immune reconstitution relative to enhancement of antigen-specific responses and (2) expansion of beneficial cell subsets and depletion of harmful effector cells. New approaches aimed at facilitating engraftment and reducing GVHD while preserving GVT effects have been developed using Tregs and mesenchymal stem cells (MSCs). In mice, two types of regulatory T cells, $CD4^+CD25^+$ T cells (Tregs) and NK T cells (NK Tregs), have been shown to prevent acute GVHD.[107-111]

Haploidentical Hematopoietic Cell Transplantation: Ongoing Novel Efforts to Improve Transplant Outcomes

Selective Allodepletion

- Unmanipulated donor lymphocyte infusions (T-cell add-backs) cause significant graft-versus-host disease (GVHD).
- Selective depletion of specific host-reactive donor T cells (instead of global T-cell depletion) may mediate graft-versus-tumor (GVT) and antimicrobial immune responses without causing significant GVHD.

Cells and Cytokines of Special Appeal (Importance)

Natural Killer Cells

- Natural killer (NK)-cell alloreactivity in GVH direction following T cell–depleted transplant can dramatically reduce leukemic relapse.
- NK-cell alloreactivity in GVH direction can lead to lower rates of graft rejection due to donor NK–mediated lysis of host residual T cells.
- NK-cell alloreactivity in GVH direction can reduce GVHD via donor NK–mediated depletion of host antigen-presenting cells (and sparing of epithelial target tissues).

Immunoregulatory T Cells

- Ex vivo expanded regulatory T cells may inhibit GVHD while enhancing immune reconstitution and facilitating GVT effects.

Mesenchymal Stem Cells

- Ex vivo expanded mesenchymal stem cells have the potential to diminish GVHD while facilitating immune reconstitution.

Cytokines and Chemokines

- A number of cytokines and chemokines and their associated monoclonal antibodies can influence effector cell development, activation, trafficking, and thereby transplant outcomes, including engraftment, GVHD, immune reconstitution, and antitumor effects.

Tregs represent approximately 5% to 10% of peripheral $CD4^+$ T cells in mice and humans and are identified by their capacity to suppress both $CD4^+$ and $CD8^+$ T-cell activation. Tregs have been shown to promote engraftment and reduce acute GVHD without loss of GVT effects.[107,108,112] In murine models, Tregs can be successfully expanded ex vivo by in vitro stimulation with allogeneic splenocytes plus IL-2. When added to the donor inoculum containing alloreactive T cells, the Treg population can prevent GVHD, enhance immune reconstitution, and reduce the risk for infection while the GVT effect is well preserved.[113] There has been considerable interest in developing approaches for expansion of human Tregs to prevent and treat GVHD.[114] Preliminary experience with expanded Tregs in humans is promising with a recent study showing that adoptive transfer of Tregs prevented GVHD in the absence of any posttransplantation immunosuppression and enhanced immunity to opportunistic pathogens.[115]

MSCs, which are multipotential nonhematopoietic progenitors and constitute only 0.001% of nucleated cells in human bone marrow,[116] have been extensively evaluated for their regenerative and immunomodulatory properties. Human MSCs have a high in vitro proliferative potential and have the capacity to differentiate into a number of mesenchymal tissues, such as bone, cartilage, and fat. MSCs have been demonstrated to inhibit T-cell alloreactivity[117-121] and prolong skin allograft survival.[122] In addition, ex vivo expanded MSCs have the potential to prevent and treat acute GVHD when used after HLA-matched or HLA-mismatched HCT.[123,124] Although the exact mechanism of immune modulation by MSC is not clearly defined, they appear to mediate their immunomodulatory effects by inhibiting interferon-γ secretion from Th1 and NK cells, increasing IL-10 secretion from Tregs and increasing IL-4 secretion from Th2 cells, thereby promoting a Th1 to Th2 shift.[120]

Cytokines and Chemokines

A number of cytokines and chemokines and their associated monoclonal antibodies can be applied to influence effector cell development, activation, trafficking, and thereby transplant outcomes, including engraftment, GVHD, immune reconstitution, and antitumor effects.[124-126] Posttransplant use of G-CSF accelerates neutrophil recovery, but studies have shown deleterious effects on immune restoration, namely, by inhibition of NK-cell and T-cell function.[127-129] Given their excellent capacity to enhance in vivo expansion of NK and T cells after T cell–depleted HCT, IL-2[130-133] and IL-18[134] potentially could improve immune reconstitution after haploidentical transplant. However, caution must be taken because, depending on the timing of administration of these cytokines, unfavorable outcomes such as exacerbation of GVHD may occur.[135,136] In one murine model, IL-7 improved immune reconstitution by enhancing thymopoiesis in addition to expanding peripheral T cells, NK cells, NK Tregs, B cells, monocytes, and macrophages.[137] However, in another model this cytokine enhanced the development of acute GVHD.[138] Keratinocyte growth factor has been shown in a murine model to improve thymic and peripheral T-cell recovery after transplant.[139] Monoclonal antibodies specific for selective cytokines and chemokines to prevent GVHD[44,140,141] and optimize GVT effects are being evaluated.[125]

Enhancement of Antigen-Specific Immune Responses

Prevention and treatment of opportunistic viral, fungal, bacterial, and parasitic infections remain formidable challenges after haploidentical HCT. For example, the failure to successfully treat viral infections, which is partly due to the limited number of nontoxic antiviral drugs, constitutes a major cause of treatment failure following haploidentical transplant. Both $CD4^+$ and $CD8^+$ cells are critical in maintaining CMV, Epstein-Barr virus, adenovirus, polyomavirus, and herpesvirus in their latent phase. Therefore adoptive immunotherapy with ex vivo expanded virus-specific cytotoxic T lymphocytes (CTLs) is being explored. Infusion of donor-derived allogeneic CMV-specific T-cell clones into recipients for prevention or treatment of CMV-related disease, without causing GVHD, has shown promising potential.[142-145] These studies also demonstrated that CMV-specific $CD4^+$ cells are important for reconstitution and maintenance of $CD8^+$ CTL responses. Encouraging early results have been achieved when ex vivo expanded allogeneic CTL clones specific for Epstein-Barr virus were used for prophylaxis and management of Epstein-Barr virus–associated diseases, including posttransplant lymphoproliferative disorder.[146-149] The identification of antigens that are specifically expressed by leukemia cells, such as PR1 by CML and AML cells, and can be recognized by T cells has led to successful ex vivo generation of leukemia-specific donor T cells (PR1-CTL) that may promote a GVT effect.[150-152] Notwithstanding the promise of these novel approaches, the large-scale therapeutic potential of adoptive transfer of ex vivo expanded antigen-specific effector cells has not yet been fully realized for a number of reasons. One reason is the short survival of the effector cells, which likely is due to factors intrinsic to the cells themselves or to the host environment into which the cells are infused.

OPTIMIZATION OF GRAFT-VERSUS-TUMOR EFFECT: ADOPTIVE CELLULAR THERAPY VIA DLI

Adoptive cellular immunotherapy using DLI has been shown experimentally and clinically to be a potent means of inducing a GVT effect

by converting mixed to full donor chimerism after allogeneic transplant.[153-155] In patients with recurrent CML after HLA-matched HCT, complete clinical and molecular remissions are achieved in the majority of patients following unmodified DLI.[156,157] A high incidence of GVHD (and marrow aplasia) has tempered the use of this approach and has led to a revision of DLI strategies, such as lowering the dose of infused T cells or giving T-cell subsets such as $CD8^+$-depleted DLI.[158] The GVHD risk likely is higher after alternative donor transplantation, and considerably smaller doses of T cells have been used in the haploidentical HCT setting.[159,160] Lewalle et al[159] reported the outcomes of escalating DLI doses after haploidentical transplantation. $CD3^+$ T-cell doses greater than 1×10^4 kg every 3 months (given to convert mixed to full chimerism) caused significant GVHD in recipients of T cell– and B cell–depleted myeloablative haploidentical HCT. Or et al[160] treated 28 patients (6 prophylactic and 22 therapeutic) with HLA-mismatched DLI. The dose range of T cells in the DLI was 1×10^2 to 1.5×10^9 kg. GVHD (median peak grade II) occurred in 13 of the 28 patients. A higher incidence of GVHD unexpectedly occurred in recipients of a 5/6 HLA-matched DLI compared to recipients of a 3/6 HLA-matched DLI. In our nonmyeloablative HCT trial, in which vigorous ex vivo and in vivo T-cell depletion are used, $CD3^+$ T-cell doses greater than 1.0×10^6 cells/kg were given in some circumstances. Because GVHD occurred in the majority of cases (most often skin-limited GVHD), future strategies will use a smaller initial DLI dose.[18] Additional dose-finding studies are required to establish the safest and most effective DLI T-cell dose and schedule following haploidentical HCT. Critical to the success of HCT will be the identification of specific cellular populations that can be administered as adoptive cellular immunotherapy (e.g., pathogen- or tumor-specific CTL) and that are capable of optimizing the separation of GVHD and GVT. An alternative approach that has been evaluated in Europe is to add back donor lymphocytes genetically engineered with a suicide gene to facilitate immune reconstitution and prevent late mortality.[161] In 50 patients who received these cells in a multicenter study, immune recovery appeared to be more rapid, and GVHD occurring in 10 was controlled by induction of the suicide gene.[161]

HAPLOIDENTICAL HEMATOPOIETIC CELL TRANSPLANTATION: NEW APPLICATIONS

Combining Haploidentical Peripheral Blood Stem Cells With Umbilical Cord Blood for Facilitation of Engraftment

Umbilical cord blood transplantation has been complicated by slow hematologic recovery and delayed immune reconstitution due in part to the relatively low number of hematopoietic progenitor cells collected and transplanted. In an attempt to facilitate hematologic recovery and reduce the complications associated with impaired immune recovery, Fernandez et al[162] cotransplanted 11 patients with umbilical cord blood cells and $CD34^+$ cell–selected haploidentical PBSCs. Rapid neutrophil recovery occurred at a median of 10 days (range, 9 to 17 days). Chimerism studies showed a predominance of the haploidentical genotype in the granulocyte and mononuclear lineages early posttransplant, followed by progressive replacement by cells of umbilical cord donor origin. Grade II or higher GVHD occurred in 4 (36%) of the 11 patients. Five of the 11 patients were alive and in complete remission 6 to 43 months posttransplant. Evaluation of immune reconstitution in this patient population demonstrated early recovery of NK cells and B cells and delayed but eventually complete recovery of $CD4^+$ and $CD8^+$ cells.[163]

Specific Tolerance Induction

Induction of donor-specific tolerance has important implications for the field of organ transplantation, which currently is limited by the complications of lifelong immunosuppressive therapy. Multiple preclinical small and large animal models have shown that sustained specific tolerance can be induced after induction of even transient mixed lymphohematopoietic chimerism.[164,165] Based on these preclinical discoveries, we have conducted clinical trials of combined related-donor bone marrow and kidney transplantation for patients with end-stage renal disease. In the first of these trials, combined HLA-matched bone marrow and kidney transplantation was performed in patients with multiple myeloma and end-stage renal disease. This experience was notable for the achievement of complete remissions in four of six patients and the occurrence of renal graft rejection (transient and reversible) in only one patient. All six patients were alive from approximately 3 to 8 years posttransplant.[7,166]

To broaden the application of this strategy, we initiated a trial of combined haploidentical bone marrow and kidney transplantation for patients with end-stage renal disease but no associated malignancy. The preparative therapy is one that we used in earlier trials of haploidentical HCT for hematologic malignancies and was notable for the uniform development of transient mixed chimerism followed by graft rejection.[18] Of the first five patients who received a combined haploidentical bone marrow and kidney transplant, four are no longer receiving immunosuppressive therapy. In vitro evidence of specific tolerance also has been demonstrated.[167]

The proof of the principle of sustained donor-specific tolerance induction through mixed lymphohematopoietic chimerism has been demonstrated clinically. Future trials will include the transplantation of other organs, including cadaveric organs, and the inclusion of fully HLA-mismatched related donors.

FUTURE DIRECTIONS

The promise of haploidentical HCT, specifically the opportunity to offer allogeneic transplantation to virtually everyone who requires it and to take advantage of the powerful GVT effect that it affords, has yet to be fully realized (see box on Haploidentical Hematopoietic Cell Transplantation: Future Direction). Although the complications of severe GVHD and graft rejection have been overcome in large part by the use of "megadose" T cell–depleted hematopoietic progenitor cells, prolonged immunodeficiency remains a formidable problem. Reduced-intensity conditioning has ameliorated early transplant-related morbidity and perhaps mortality but has been associated with a higher relapse probability and no clear advantage in terms of restoration of effective immunity. Vigorous pan–T cell depletion of the graft dramatically reduces the incidence of acute GVHD but delays immune reconstitution, resulting in a high incidence of opportunistic infections and disease relapse.

The future of haploidentical HCT relies on the ability to modulate the cellular content of the graft and the posttransplant cellular environment, to separate GVHD and GVT, and to rapidly restore effective immunity (shown schematically in Fig. 107-1). Strategies such as selective allodepletion of the graft or enrichment for (or

Haploidentical Hematopoietic Cell Transplantation: Future Directions

Approaches involving T-cell depletion or modulation are likely required to prevent severe graft-versus-host disease. Therefore we will need the following:

- Improved immune reconstitution, such as pathogen-specific cytotoxic T lymphocytes (CTLs) and better infectious disease monitoring
- Strategies to prevent disease relapse, such as adoptive natural killer cells, regulatory T cells, and tumor-specific CTLs
- Prospective, multicenter trials to define optimal regimens and post–hematopoietic cell transplantation care

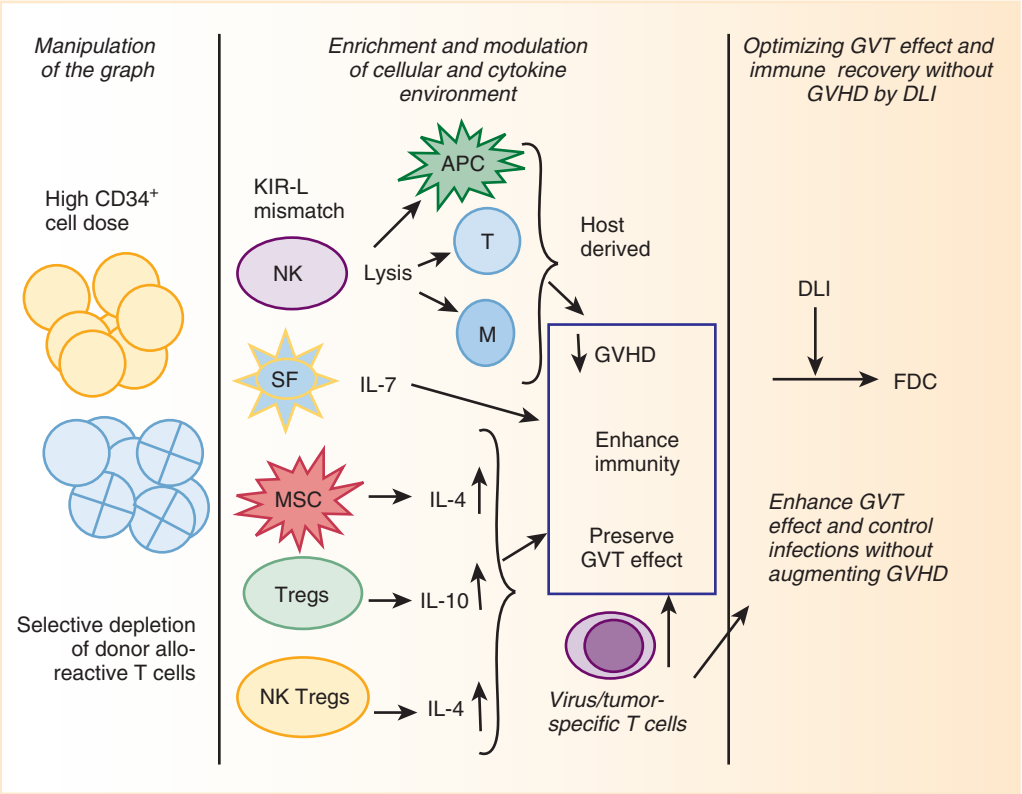

Figure 107-1 SCHEMA OF A STRATEGY TO OPTIMIZE THE OUTCOMES OF HAPLOIDENTICAL HEMATOPOIETIC CELL TRANSPLANTATION. *Manipulation of the graft:* A high CD34$^+$ cell dose will likely improve donor engraftment by overcoming host-mediated resistance; selective ex vivo depletion of donor alloreactive T cells may reduce the incidence of severe acute graft-versus-host disease (GVHD) while preserving a graft-versus-tumor (GVT) effect and improving immune recovery. *Enrichment and modulation of cellular and cytokine environment:* Killer immunoglobulin-like receptor ligand (KIR-L) mismatching in the GVH direction will prompt donor natural killer (NK) cells to promote engraftment by attacking host T cells (T), diminish acute GVHD by depleting host antigen-presenting cells (APC) while eliminating host-derived malignant cells (M). Ex vivo expanded NK cells, mesenchymal stem cells (MSC), regulatory T cells (Tregs), NK Tregs, and soluble factor (SF; IL-7) will further augment donor engraftment, innate and adaptive immune responses, and reduce GVHD while not impairing GVT effects. MSC and NK Tregs, via IL-4 production, will skew donor T cells toward an antiinflammatory Th2 phenotype that is associated with reduced GVHD. *Optimizing GVT effect and immune recovery without GVHD by unmodified donor leukocyte infusion (DLI):* Ex vivo engineered tumor antigen and pathogen (virus)-specific donor-derived T cells (both cytotoxic T lymphocytes and CD4 cells) can be used to prevent and/or treat relapse of an underlying malignancy and opportunistic infections, respectively. In some circumstances, unmodified DLI may be used to convert mixed chimerism to full donor chimerism (FDC), probably enhancing a GVT effect without augmenting GVHD.

addition of) cell populations such as Tregs or MSCs to the graft may achieve effective protection from GVHD while imparting effective antitumor and antiinfective immunity.

Following the transplant, administration of specific cellular populations or soluble factors may affect the separation of GVHD and GVT effect. Unmanipulated DLI may still be considered at certain times to convert the mixed chimerism to full donor hematopoiesis in an effort to achieve an early GVT effect and facilitate early reconstitution. The adoptive transfer of allogeneic cytotoxic T cells that are specific for viral or tumor antigens may be other strategies for addressing the problems of infection and disease relapse. Other cellular populations, such as NK or NK T regs cells or MSC, may favorably influence the balance of GVHD and immune reconstitution. The future of haploidentical transplant depends on our expanding knowledge of the cellular populations and soluble factors that determine the separation of GVHD and GVT effect and our ability to modulate the cellular content of the graft and the post-transplant environment to improve disease-free and overall survival probabilities.

CHAPTER 108

UNRELATED DONOR CORD BLOOD TRANSPLANTATION FOR HEMATOLOGIC MALIGNANCIES

Doris M. Ponce and Juliet N. Barker

Cord blood (CB) is now routinely used as an alternative stem cell source for unrelated donor allogeneic stem cell transplantation. In the late 1980s, Broxmeyer and colleagues[1] reported that CB is a rich source of hematopoietic stem cells (HSCs) and progenitors, setting the stage for the first related donor CB transplantation (CBT) in 1988.[2] Subsequently, placental blood banking programs were initiated in 1992 to 1993 in New York, Milan, Dusseldorf, and Paris.[3,4] The first unrelated donor CBT was performed in 1993, and the first unrelated donor CBT series were published in 1996.[5,6] Public CB banks have since grown in number with an estimated 600,000 public CB units banked globally.[7] Furthermore, the number of CBT continues to increase with an estimated 20,000 now performed.[7]

The use of CB stem cells has several benefits. Given it is a cryopreserved product, it has rapid accessibility, does not carry the risk of donor unavailability, and has the advantages that the admission of the patient revolves around the patient's readiness for transplantation and not the availability of the donor. Barker et al[8] reported that recipients of CB grafts were transplanted a median of 25 days earlier than unrelated donor transplant recipients. This is particularly advantageous for patients in need of an urgent transplant. Another benefit is the reduced stringency of the required human leukocyte antigen (HLA) match afforded by the naïve neonatal immune system. This has facilitated the extension of transplant access, especially to racial and ethnic minorities. A recent prospective analysis conducted at Memorial Sloan-Kettering Cancer Center (MSKCC) of 525 patients undergoing combined unrelated donor and CB unit searches demonstrated that 53% of patients from European ancestry but only 21% of non-Europeans had a 10/10 HLA-matched unrelated donor identified (P <.001).[9] By contrast, 5-6/6 HLA-matched CB units were identified for a high proportion of all patients (79% of Europeans and 71% of non-Europeans). Of the 269 unrelated volunteer donor transplant recipients, only 23% had non-European origins, but 56% of CBT recipients had non-European ancestry (P <.001) (Fig. 108-1). Thus, CB is frequently able to provide a suitable graft regardless of patient racial or ethnic background.

SINGLE UNIT CORD BLOOD TRANSPLANTATION

Engraftment

Unrelated donor CBT was initiated using single-unit grafts. Studies have demonstrated that higher cell dose and better donor–recipient HLA match are independent factors associated with improved neutrophil engraftment.[10-17] The 1997 Eurocord analysis was the first large series reporting on 143 related and unrelated donor CBT recipients. In unrelated donor CBT recipients, improved neutrophil and platelet engraftment were both associated with a higher total nucleated cell (TNC) dose above the median of 3.7×10^7/kg and donor–recipient HLA match.[10] In 1998, Rubinstein et al[11] confirmed these findings in an analysis of 562 CBT facilitated by the New York Blood Center (NYBC) as did an updated analysis by Gluckman and Rocha in 2004.[15] In 2002, Wagner et al[13] reported that infused $CD34^+$ cell dose was superior to infused TNC dose in determining the success of neutrophil and platelet engraftment in an analysis of 102 CBT (median age, 7.4 years) with recipients of units with less than 1.7×10^5 $CD34^+$ cells/kg having a significantly lower neutrophil engraftment incidence of 72% at a median of 34 days compared with higher cell doses ($P < 0.01$).

These analyses have the limitation that cell dose and HLA match are analyzed separately and yet these graft characteristics must be considered together in the selection of individual units. In 2009, Rocha and Gluckman[18] reported on 925 recipients of single-unit CBT transplanted for malignant disease and found that neutrophil engraftment was related to the number of cells infused (P <.0001) and HLA match with a significant difference between zero and one (81%), two (75%), and three and four (63%) HLA disparities (P = .037). The role of HLA match was partially abrogated by an increase in cell dose except for recipients of highly mismatched grafts. In 2010, Barker et al[17] analyzed the combined effect of TNC dose and donor–recipient HLA match in 1061 single-unit CBT recipients transplanted for hematologic malignancies after myeloablative conditioning. The best neutrophil engraftment was associated with a fully HLA-A, -B antigen, and -DRB1 matched unit or a cryopreserved TNC greater than 10.0×10^7/kg with one or two mismatches. The worst was with a unit with three mismatches or a cryopreserved TNC below 2.5×10^7/kg with one or two mismatches (Fig. 108-2). There was no difference in neutrophil engraftment in recipients of one versus two mismatched units, and in this setting, the TNC dose determined neutrophil engraftment.

Graft-Versus-Host Disease

Single-unit CBT is associated with a lower than expected incidence of graft-versus-host disease (GVHD) for the degree of donor–recipient HLA mismatch, which allows use of units with a less stringent HLA match (i.e., only a 4-6/6 HLA-A, -B antigen, -DRB1 allele match). Incidences of grades II to IV acute GVHD have been reported between 10% and 50% and likely vary according to the GVHD prophylaxis used and the inclusion of antithymocyte globulin in the conditioning.[10,17,19-23] As with the transplantation of adult donors, the major graft determinant of acute GVHD is the HLA match, although with CB, the permissible mismatch is considerably greater than can be tolerated with HSC transplantation from adult donors.

Although an effect of HLA mismatch could not be demonstrated in early series of unrelated donor CBT,[10,11,13,24] the recent large NYBC retrospective analysis of 1061 single-unit CBT recipients demonstrated that recipients of matched CB units had significantly less grade III to IV acute GVHD and that increasing mismatch was associated with a progressively increased risk of severe acute GVHD.[17] There was also an association between the degree of mismatch and chronic GVHD, although this only reached significance in recipients of units with three mismatches.[17] Kurtzberg et al[22] have reported that high-resolution matching at HLA-A, -B, and -DRB1 alleles was protective with significantly higher incidence of grades II-IV (P = .02) and III to IV (P = .02) acute GVHD in recipients of units with less than 5/6 allele match. A recent report by Eapen et al[25] in 803 recipients of single CB units that analyzed the effect of match at HLA-A, -B, -C at intermediate resolution and DRB1 at allele resolution did not show a significant effect of HLA-match for grades II to IV acute GVHD, but high-resolution matching was not examined at HLA class I.

Relapse

During the early years of CBT, there was concern that the neonatal immune system would not adequately protect against relapse. However, multiple series have demonstrated a strong protection against relapse after CBT with the major determinant of relapse being the recipients' disease status.[13,22,23,26] The NYBC series of 1061 single-unit CBT recipients showed no association between HLA match grade and the incidence of relapse, and subgroup analysis in only relapsed patients, only remission patients, and only those who engrafted also failed to demonstrate any association.[17] However, the 2011 analysis of Eapen et al[25] (n = 803) showed a lower relapse incidence after CBT mismatched at more than one loci compared with recipients of units matched at HLA-A, -B, -C and -DRB1, although the number of mismatched loci had no effect. The reason for the disparity in the findings of these two studies is not known, and this area requires further investigation before definitive conclusions can be drawn.

Transplant-Related Mortality and Survival

Early series of single-unit CBT demonstrated high transplant-related mortality (TRM) and consequently poor survival after single-unit CBT. This likely related to the high-risk nature of the patient population and standards of supportive care as well as the characteristics of the transplanted units. Factors such as disease status and recipient cytomegalovirus (CMV) positivity are strong determinants of survival after single-unit CBT.[22] From the standpoint of the graft, both TNC dose and HLA-match influence TRM and survival. In addition to low TNC dose being associated with increased TRM and decreased survival,[10,11,13,17] the 68 adult patient analysis of Laughlin et al[27] and the Wagner et al[13] 102 patient analysis demonstrated a higher $CD34^+$ cell dose (>1.2 and 1.7, respectively) were associated with significantly improved disease-free survival (DFS). Similarly, studies have identified increasing HLA-mismatch is significantly associated with increased TRM and lower survival.[13,17,21] The 2010 NYBC analysis of combined TNC dose and HLA match showed that recipients of 6/6 HLA-matched units had the lowest TRM and best survival regardless of the dose at least within the dose range tested (Fig. 108-3).[17] Recipients of units with 1 HLA-mismatch and a TNC dose 2.5 to 4.9 × 10^7/kg had a similar TRM as those receiving units with two mismatches and a TNC greater than 5.0 ×10^7/kg despite the higher cell dose in the latter group (see Fig. 108-3). Recipients of single units with one or two mismatches and a TNC below 2.5 × 10^7/kg had very high TRM and poor survival.

In the recent 2011 Eapen series evaluating the contribution of HLA-C matching after single unit CBT, patients matched at HLA-A, -B, and -DRB1 had a higher TRM if mismatched at HLA-C (n = 23; hazard ratio [HR], 3.97; P = .18) as compared with those matched at all 4 loci (n = 69).[25] TRM was also higher in 5/6 but 6/8 matched CBT recipients mismatched at one of HLA-A, -B or -DRB1 plus HLA-C (n = 234; HR, 1.70; P = .029) compared with those

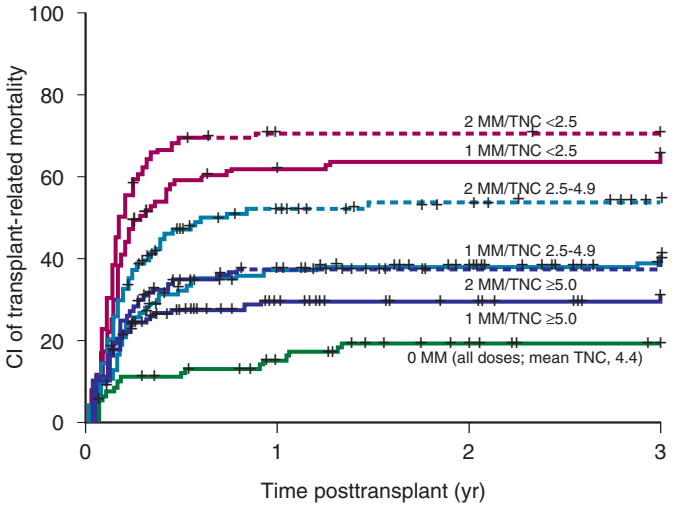

Figure 108-3 CUMULATIVE INCIDENCE (CI) OF TRANSPLANT-RELATED MORTALITY (TRM) ACCORDING TO THE COMBINED TOTAL NUCLEATED CELL (TNC) DOSE AND HUMAN LEUKOCYTE ANTIGEN MISMATCH AFTER SINGLE-UNIT MYELOABLATIVE CORD BLOOD TRANSPLANTATION. *MM,* Mismatched. *(From Barker JN, Scaradavou A, Stevens CE: Combined effect of total nucleated cell dose and HLA match on transplantation outcome in 1061 cord blood recipients with hematologic malignancies.* Blood *115:1843, 2010.)*

who were 5/6 and 7/8 matched (i.e., when there was a single HLA mismatch at -A, -B, or -DRB1 but a match at -C; $n = 127$). This study suggests that HLA-C matching is an important determinant of survival and should be considered in unit selection algorithms.

Comparison of Single-Unit Cord Blood Transplantation and Adult Donor Allografts

Although the use of CBT as an alternative HSC source has increased substantially, no randomized studies evaluating survival after CBT versus adult donor allografts have yet been reported. Retrospective comparisons have demonstrated varying results depending on whether the series evaluated children or adults and if matched versus mismatched unrelated volunteer donors were included. Selected series are summarized in Table 108-1. In 2007, Eapen and colleagues[21] compared the outcomes of pediatric single-unit CBT with those of unrelated volunteer bone marrow (BM) recipients who were transplanted for the treatment of acute leukemia. Compared with the recipients of 8/8 allele matched unrelated donor BM transplantation (BMT), the 5-year leukemia-free survival in recipients of one or two HLA-mismatched CBT was similar. Notably, however, a significantly higher leukemia-free survival was observed in recipients of 6/6 HLA-matched units. Interestingly, TRM was similar in 6/6 HLA-matched and 5/6 HLA-matched high cell dose compared with that of allele-matched unrelated donor recipients' transplant ($P = .0659$ and .1332, respectively). By contrast, TRM was higher in recipients of one antigen HLA-mismatched low cell dose and two antigen HLA-mismatched of any cell dose compared with allele-matched unrelated donor recipients ($P = .0455$ and .0003, respectively).

A similar analysis done in adult patients with acute leukemia demonstrated that single-unit CBT recipients had a higher TRM compared with recipients of 8/8 HLA-matched unrelated donor transplants but a similar TRM to that of 7/8 HLA-mismatched unrelated donor transplant recipients.[23] The Japanese group of Takahashi et al[20] compared CBT recipients with unrelated donor BM or peripheral blood HSC transplantation for the treatment of hematologic malignancies. They demonstrated a slower neutrophil recovery in CBT recipients but a similar rate of neutrophil engraftment. The incidences of grades III to IV acute GVHD and extensive chronic GVHD were higher after unrelated donor transplantation. No differences were demonstrated in TRM, relapse, or DFS between the groups. Atsuta et al[28] conducted a disease-specific analysis comparing CBT to unrelated donor BMT in patients with acute leukemia. The patients had similar age distribution, and all received myeloablative conditioning. In the acute myeloid leukemia group, there was a similar relapse rate but higher TRM in CBT recipients, resulting in lower survival, but similar relapse and survival rates were seen in the acute lymphoblastic leukemia group. The risk of developing extensive chronic GVHD was lower in CBT recipients.

DOUBLE-UNIT CORD BLOOD TRANSPLANTATION

The transplantation of HSC from more than one donor is an approach that was originally reported by Mathé et al,[29] who infused multiple aliquots of BM from different donors. In 1972, Ende and Ende[30] published the first case of allogeneic CBT using multiple small CB units. Subsequently, double-unit CBT (DCBT) was formally investigated by the University of Minnesota as a method to augment the graft cell dose. These investigators demonstrated the safety and feasibility of this approach.[31] Barker et al reported two series of DCBT after myeloablative[32] and nonmyeloablative[33] conditioning in patients with high-risk hematologic malignancies. The myeloablative series evaluated 23 patients (median age 24 years) and demonstrated that all evaluable patients achieved donor-derived neutrophil engraftment at a median of 23 days. The striking finding of this report was the high level of engraftment despite sustained hematopoiesis being mediated by a single donor in nearly all patients and the high 1-year overall survival of 72%. The non-myeloablative series demonstrated that it was possible to engraft CB after conditioning with cyclophosphamide 50 mg/kg, fludarabine 200 mg/m^2, and 200 cGy of total body irradiation. In 2007, Brunstein et al updated the non-myeloablative experience in 110 adults (17 received single-unit and 93 DCBT) and demonstrated neutrophil engraftment in 92% but a higher probability of 3-year event-free survival of 39% in DCBT recipients compared with 24% in single-unit recipients ($P = .05$).[34] The high incidences of donor-derived neutrophil engraftment have been subsequently replicated at other centers, including MSKCC.[35] A series of 54 DCBT recipients (median, age 42; range, 7-66 years) transplanted with either myeloablative ($n = 35$) or nonmyeloablative ($n = 19$) conditioning demonstrated a high engraftment rate of 94% and overall survival of 65% at 1-year posttransplant[35] despite the relatively low infused TNC dose of 2.52×10^7/kg of the unit responsible for engraftment.

Determinants of Unit Dominance

The determinants of DCBT unit dominance remain to be fully elucidated. Better HLA match, ABO group, and higher infused TNC or CD34$^+$ cell doses have not predicted which unit will win. Current evidence suggests that unit dominance is predominantly immune mediated, although unit hematopoietic potential can also play a role (Table 108-2).

Host Factors as Determinants of Unit Dominance

Eldjerou et al[36] were the first to report both in vitro and in vivo studies of DCBT using aliquots of cells from each unit of a clinical double-unit CB allograft and correlation of the laboratory findings with patient engraftment. The experimental design used nonobese diabetic severe combined immunodeficient interleukin-2 receptor gamma null (NOD/SCID/IL2R-γ^{null}) mice and demonstrated that the engrafting unit in the mice correlated with clinical engraftment in 18 of 21 cases ($P < .001$). Thus, given the concordance of the human and murine engraftment, these findings suggest that unit dominance is not related to host-versus-graft factors. Brunstein et al[37] evaluated the effect of donor-specific anti-HLA antibodies in 126 DCBT recipients and found no correlation with the speed of engraftment or unit dominance. Similar findings have been documented in MSKCC

DCBT recipients transplanted for hematologic malignancies (J. Barker, unpublished data, 2011). This is further evidence that host factors do not play a major role in unit dominance.

Hematopoietic Potency as a Determinant of Unit Dominance

Although the infused $CD34^+$ cell or colony-forming unit (CFU) dose has not been associated with unit dominance, Scaradavou et al[38] have shown that hematopoietic potential can sometimes determine unit dominance. These investigators evaluated the effect of the percentage of viable $CD34^+$ cells postthaw in 46 DCBT recipients and found that engrafting units almost always had a high $CD34^+$ cell viability greater than 75%, but units with lower $CD34^+$ cell viability were very unlikely to engraft ($P = .0006$). Low $CD34^+$ cell viability also correlated with CFU potential. Thus, one mechanism by which DCBT can favorably influence engraftment is that the infusion of two units increases the chance that at least one unit with engraftment potential will be administered. Interestingly, in the only patient that had graft failure in this series, both units had poor $CD34^+$ cell viability.

Georges et al[39] have confirmed that higher $CD34^+$ cell viability was the only graft variable to predict unit dominance in a canine model of DCBT. By contrast, Eldjerou et al[36] evaluated the hematopoietic potential of each unit in vitro as measured by colony-forming cell and cobblestone area–forming cell content using either mononuclear cells or $CD34^+$ cells, and this did not correlate with clinical unit dominance with the contribution of each unit in co-cultures being concordant with the clonogenic efficiency of that unit when cultured alone. Thus, although $CD34^+$ and CFU dose may not predict unit dominance, damage to the unit as reflected by a low percentage of viable $CD34^+$ cells is associated with impaired engraftment potential in large animal models and humans.

Immune Factors as Determinants of Unit Dominance

Analysis of early DCBT series showed that higher infused $CD3^+$ cell dose correlated with the engrafting unit.[9] This has been subsequently confirmed in recent studies[40] supporting the role of T cells in unit dominance. Murine models have also suggested that an immune mechanism accounts for unit dominance. Kim et al[41] demonstrated that despite each unit engrafting alone, co-infusion of mononuclear

Table 108-2 Potential Determinants of Unit Dominance After Double-Unit Cord Blood Transplantation

Potential Mechanism	Reference	Finding	Implications
Host factors	Eldjerou et al[36]	Unit dominance in mice correlated with clinical engraftment.	Host factors do not influence unit dominance.
	Brunstein et al[37]	Donor specific anti-HLA antibodies had no influence on unit dominance.	
Unit factors Hematopoietic potential	Scaradavou et al[38]	Infused TNC/kg, $CD34^+$/kg, and CFU doses were not associated with unit engraftment. However, units with low $CD34^+$ viability were very unlikely to engraft.	Infused $CD34^+$ cell dose and CFU, CFC, or CAFC content do not directly influence unit dominance, but poor-quality units are very unlikely to engraft in humans.
	Eldjerou et al[36]	In vitro CFC and CAFC content did not correlate with unit dominance.	
Immune factors	Barker et al,[32] Scaradavou et al,[38] Avery et al[40]	Higher infused $CD3^+$ cell dose is associated with unit dominance.	Graft-versus-graft interactions dictate unit dominance.
	Kim et al[41]	DCBT with MNC associated with unit dominance whereas co-engraftment achieved with lineage depletion or MSC infusion.	
	Yahata et al[42]	Mixed chimerism achieved by $CD34^+$ selection.	
	Eldjerou et al[36]	Loss of unit dominance with $CD34^+$ DCBT restored with addition of $CD34^-$ cells.	
	Delaney et al[44]	Unmanipulated unit is dominant when co-infused with T-cell depleted expanded CB.	
	Gutman et al[43]	Dominant unit $CD8^+$ T cells directed against the nondominant unit detected in patients with single unit dominance.	
	Avery et al[40]	High level of unit-unit match associated with increased likelihood of co-engraftment.	
	Brunstein et al[45]	Higher prevalence of dual chimerism after Treg infusion.

cells as a double-unit graft was associated with predominance of one CB unit in NOD/SCID mice. Unit dominance could be mitigated (and engraftment of both units achieved) with either lineage depletion of the units or cotransplantation of third-party BM-derived mesenchymal stromal cells. Yahata et al[42] replicated this observation in NOD/SCID/IL2R-γ^{null} mice and found that the co-infusion of mononuclear cells from two CB units resulted in single unit dominance but mixed chimerism could be generated by $CD34^+$ cell selection. Additional experiments by this group extended this observation by demonstrating that unit dominance was T cell–mediated and specifically involved both $CD4^+$ and $CD8^+$ cells. The study of Eldjerou et al[36] found that NOD/SCID/IL2R-γ^{null} murine DCBT resulted in single unit dominance that correlated with clinical engraftment in 18/21 patients. Furthermore, murine DCBT using $CD34^+$ cells was associated with loss of both unit dominance and clinical correlation, and addition of $CD34^-$ cells from only one of the two units restored unit dominance but with engraftment being mediated by the origin of the $CD34^-$ cells regardless of which unit engrafted in the patient. These findings suggest that unit dominance is an in vivo event that is mediated by graft-versus-graft interactions.

Additional evidence in favor of an immune basis for unit dominance comes from the study by Gutman et al,[43] who identified $CD8^+$ T cells derived from the dominant unit that recognized the nondominant unit were present in the peripheral blood 28 days after transplantation in nine of 10 DCBT recipients engrafting with single units regardless of the conditioning regimen. Interestingly, the three patients who had persistent mixed chimerism also did not develop an alloreactive $CD8^+$ T-cell response. Furthermore, it can be hypothesized that the failure of sustained engraftment of ex vivo expanded CB units in clinical trials of DCBT in which one of two units is expanded is not attributable to failure to expand or maintain sufficient progenitors in the manipulated unit but because the expanded unit is T cell depleted and therefore cannot compete with a T cell replete unmanipulated unit.[44] Moreover, Brunstein et al[45] evaluated the safety of ex vivo expanded regulatory T cells (Tregs) in DBCT recipients and found an increased prevalence of co-engraftment of both units (dual donor chimerism), suggesting that graft-versus-graft interactions could be ameliorated by suppressing T-cell responses.

Clinical data from Avery et al[40] have demonstrated a role of HLA-match in unit dominance. Interestingly, in this analysis of 84 DCBT recipients, the dominant units were not necessarily better HLA matched to the recipient compared with the nondominant unit of a double-unit pair (Fig. 108-4). However, the unit–unit HLA match influenced the length of time the ultimately nonengrafting unit was able to be detected. Specifically, recipients of double-unit grafts in whom the unit–unit HLA match was 7/10 or greater HLA-allele matched were significantly more likely to have initial co-engraftment and transient persistence of the ultimately nonengrafting unit with one patient having sustained engraftment of both units long term. By contrast, recipients of units highly mismatched (<6/10) to each other were more likely to have engraftment with only a single unit. This is likely because of an enhanced unit-versus-unit immune response, whereas closely HLA-matched units are more likely to be relatively tolerant of each other, and in this setting, at least transient co-engraftment is possible.

Taken together, these findings suggest that unit dominance likely involves a complex interplay of hematopoietic potential as suggested by the role of $CD34^+$ cell viability as well as immune factors that are likely T cell mediated because no role for natural killer (NK) cells has been identified to date.[46] Future studies need to elucidate the specific cell population mediating the graft-versus-graft effect in the setting of the transplantation of two units with adequate engraftment potential.

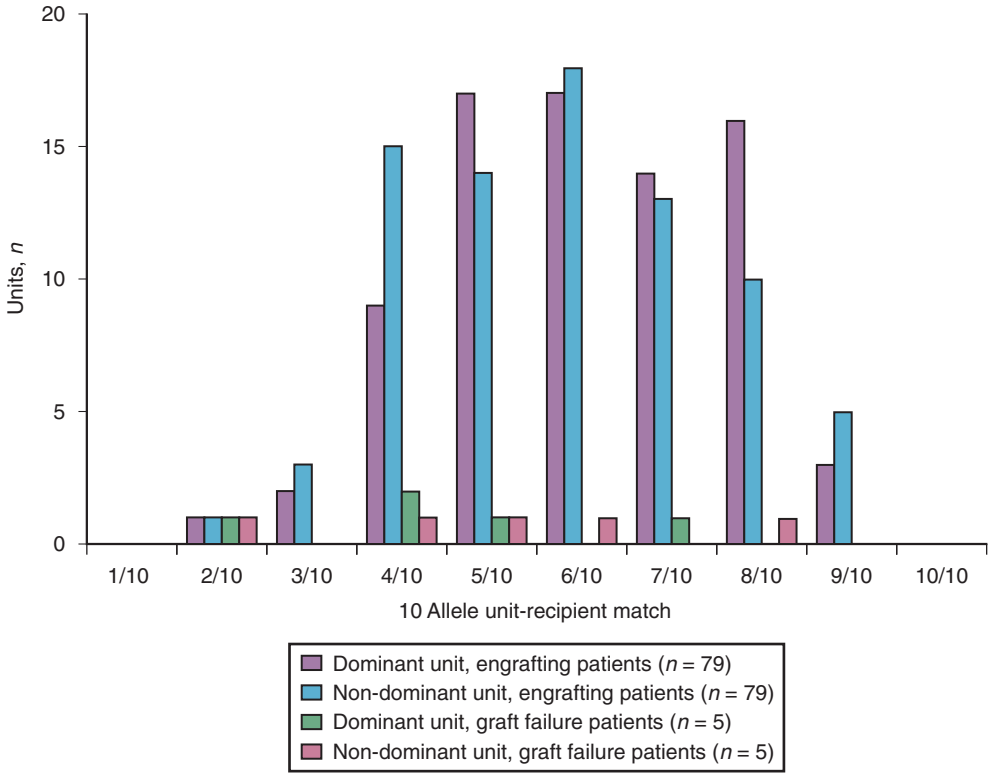

Figure 108-4 INFLUENCE OF HIGH RESOLUTION UNIT-RECIPIENT HUMAN LEUKOCYTE ANTIGEN MATCH ON SUSTAINED DONOR ENGRAFTMENT AFTER DOUBLE-UNIT D BLOOD TRANSPLANTATION ($n = 84$). The engrafting units were not better matched to the recipient. *(From Avery S, Shi W, Lubin M, et al: Influence of infused cell dose and HLAmatch on engraftment after double-unit cord blood allografts.* Blood *117:3277, 2011.)*

Determinants of Speed and Success of Engraftment After Double-Unit Cord Blood Transplantation

The use of double-unit CB grafts is now a standard approach to augment cell dose, although whether DCBT improves engraftment compared with single-unit CBT is yet to be definitively proven. Barker et al[35] reported the analysis of 54 DCBT recipients with hematologic malignancies who received either myeloablative ($n = 35$) or nonmyeloablative ($n = 19$) conditioning and found a high incidence of sustained donor engraftment of 94% (95% confidence interval [CI], 87-100) by day 50 (Fig. 108-5). This is in contrast to the reported engraftment after myeloablative conditioning in single-unit CBT series of 65% to 88%.[13,19,22,23,26,34] The Avery MSKCC series updated their experience in 2011 with the analysis of the influence of infused cell dose on engraftment after DCBT in 84 patients.[40] A high incidence of sustained donor engraftment was achieved among myeloablative ($n = 61$) and nonmyeloablative ($n = 23$) conditioning recipients of 93% and 96%, respectively. Interestingly, sustained donor neutrophil engraftment was mediated by 1 unit in the majority of patients regardless of conditioning intensity. Notably, initial engraftment of both units did not increase the likelihood or speed of neutrophil recovery ($P = .71$), suggesting that this is not the mechanism of enhanced engraftment after DCBT.

This analysis also demonstrated that in recipients of myeloablative conditioning, a higher infused cell dose (TNC, $CD34^+$) and CFU dose of the dominant unit was associated with a higher incidence of sustained donor engraftment and improved speed of neutrophil recovery (Fig. 108-6) whereas the doses of the non-dominant unit had no impact. Neutrophil recovery was faster with all patients engrafting if the dominant unit had a $CD34^+$ cell dose of 0.9×10^5/kg or greater compared with lower cell doses ($P = .0008$). A higher infused total (unit 1 + unit 2) graft TNC and $CD3^+$ cell dose was also associated with improved engraftment, suggesting that the nonengrafting unit may help facilitate the engraftment of the dominant unit in a dose-dependent fashion. By contrast, unit–recipient HLA match and unit–unit HLA match evaluated at 6 HLA loci or 10 HLA alleles had no association with engraftment speed or success. As seen in single-unit CBT, however, analysis of large numbers of patients are required to determine the role of HLA match in DCBT engraftment rates.

Graft-Versus-Host Disease After Double-Unit Cord Blood Transplantation

DCBT may be associated with an increased incidence of acute GVHD, especially if performed without antithymocyte globulin.[47,48] In a retrospective analysis by MacMillan et al[47] comparing the incidence of acute GVHD in single-unit ($n = 80$; median age, 23 years) and double-unit ($n = 185$; median age, 45 years) CBT recipients, the incidence of grades II to IV acute GVHD of 39% after single-unit grafts was significantly lower than the 58% incidence after DCBT ($P < .01$).[47] However, the increased risk was predominantly accounted by grade II skin acute GVHD, and the overall incidence of grades III to IV acute GVHD was similar among the groups (19% vs. 18%). However, GVHD has emerged as a major cause of morbidity and mortality after DCBT. A recent MSKCC analysis of 75 DCBT recipients demonstrated that GVHD was the second most common cause of TRM after organ failure.[48]

Ponce et al[49] evaluated the incidence and characteristics of GVHD in 101 DCBT recipients with hematologic malignancies. Patients received either myeloablative ($n = 76$; 75%) or nonmyeloablative ($n = 25$; 25%) conditioning. GVHD prophylaxis consisted of a calcineurin inhibitor and mycophenolate mofetil, and no patient received antithymocyte globulin. The cumulative incidence of grade II to IV acute GVHD by day 100 was 50% (95% CI, 40-60) with 26% (95% CI, 16-35) having grade III to IV disease. The median onset was 39 days (range, 14-99), and the organ most commonly affected was the gastrointestinal tract followed by the skin. With a median follow-up of 24 months (range, 4.5-60.5), the 1-year cumulative incidence of ongoing late acute or chronic GVHD was 35% (95% CI, 26-45), and the 1-year progression-free survival (PFS) was 65% (95% CI, 56-75). Series of DCBT incorporating antithymocyte globulin have demonstrated lower rates of GVHD. For example, Cutler et al[50] reported an overall incidence of grade II to IV acute GVHD of 9.4% and chronic GVHD of 12.5%. Although the incidence of acute GVHD after DCBT is increased with the omission of antithymocyte globulin in the pretransplant conditioning, its use is associated with a higher risk of serious infections, including serious Epstein-Barr virus (EBV)–related complications,[51] delayed immune reconstitution,[52] and an increased risk of TRM,[34,53] and may also increase the risk of relapse.[54] Thus, better understanding of the pathophysiology of GVHD after DCBT is needed to facilitate improved prevention and treatment of this disease.

Relapse

Multiple retrospective series of DCBT have been associated with a reduced incidence of relapse in patients with leukemia and lymphoma, suggesting an enhanced graft-versus-malignancy effect.[34,53,55] Verneris et al[55] analyzed the risk of acute leukemia relapse in 177 recipients of myeloablative CBT (47% single-unit and 53% double-unit CBT) and found that the 19% relapse risk in DCBT recipients in first or second remission was lower than that 34% relapse risk in single-unit recipients ($P = .03$). Notably, the lower risk of relapse was not influenced by conditioning regimen, GVHD prophylaxis, engrafting unit–recipient HLA match, infused cell dose, or development of acute or chronic GVHD in multivariate analysis. The University of Minnesota group also analyzed 110 nonmyeloablative CBT recipients (17 single-unit and 93 double-unit grafts) and found a trend toward a reduced relapse risk among those receiving DCBT (30% vs. 41%; $P = .07$).[13] Eurocord-Netcord investigators have published similar findings in patients with lymphoid malignancies.[53] The

Barker et al 2011 series of 75 DCBT recipients (31% children and 69% adults) transplanted for high-risk acute leukemia or myelodysplasia demonstrated a strikingly low 2-year incidence of relapse of 9% in children and 6% in adults.[56] It is possible that the increased $CD3^+$ cell dose or unit–unit interactions may mediate an enhanced graft-versus-malignancy effect after DCBT. Further investigation of the potential mechanisms accounting for these observations should be a priority.

Transplant-Related Mortality and Survival

The MSKCC series of 75 DCBT recipients of either myeloablative (n = 53; 71%) or nonmyeloablative (n = 22; 29%) conditioning demonstrated that the 2-year TRM of 25% was almost entirely accounted for by patients dying in the first 6 months after transplant.[48] Thus, DCBT recipients who survive the first 180 days were very unlikely to die of transplant-related causes. Interestingly, Sauter et al[57] demonstrated steady immune recovery from day 120, which likely contributes to this protection against late mortality.

The Minnesota series of 177 myeloablative CBT recipients (84 single-unit and 93 double-unit grafts) transplanted for the treatment of acute leukemia demonstrated a 5-year overall rate and DFS of 47% and 46%, respectively.[55] The MSKCC series of 75 DCBT recipients with lymphoid and myeloid malignancies demonstrated a 2-year overall and PFS of 65% and 55%, respectively.[48] Barker et al[56] have evaluated 75 DCBT recipients (23 children and 52 adults) with high-risk acute leukemia, myelodysplasia, and myeloproliferative disorder and found a 2-year DFS of 78% in children and 64% in adults. Multivariate analysis revealed that CMV serostatus was the only significant determinant of DFS. Brunstein et al[58] reported the outcomes of 50 DCBT recipients in a multicenter study of nonmyeloablative CBT for the treatment of hematologic malignancies. The 1-year overall survival and PFS were 54% and 46%, respectively.

Comparison of Double-Unit Cord Blood Transplantation With Adult Donor Allografts

A number of recent retrospective series have shown similar survival after DCBT and adult donor transplantation, supporting the use of double-unit grafts as an alternative stem cell source (Table 108-3). The 2010 combined series of the Fred Hutchinson Cancer Research Center and the University of Minnesota compared DCBT (n = 128), matched related (n = 204), matched unrelated (n = 152), and mismatched unrelated (n = 52) donor recipients for the treatment of acute or chronic myeloid leukemia.[59] They found that neutrophil recovery was delayed at least 1 week but grade II to IV acute GVHD was lower after DCBT. The 2-year TRM was higher in DCBT recipients, but when the analysis was restricted to DBCT recipients with earlier neutrophil engraftment (median <26 days), the TRM incidence was similar among the groups. When compared with adult unrelated donor transplantation, TRM risk was similar. Interestingly, the 5-year DFS was not different by donor type.

Similarly, Ponce et al[48] have compared 75 DCBT recipients with 108 related donor and 184 unrelated donor transplant recipients with hematologic malignancies. They demonstrated that the median time to neutrophil recovery was delayed in myeloablative CBT recipients compared with other stem cell sources. However, the 2-year PFS was similar among the groups (P = 0.573) (Fig. 108-7). These results are striking given the median match of the CB units to the patient was 6/10 (range, 2-9/10) at high resolution and the median infused $CD34^+$ dose was 0.09×10^6/kg/unit. A Eurocord-Netcord analysis compared patients with lymphoid malignancies who received either CBT (44 single-unit and 31 double-unit grafts) or matched unrelated donors (n = 284) after reduced-intensity conditioning.[60] They found a lower incidence of neutrophil engraftment in CBT recipients but similar rates of acute GVHD, TRM, and DFS. Relapse rates were also similar despite more aggressive lymphoid histologies and refractory disease in the CBT group. Overall, these findings are encouraging and suggest the feasibility of conducting a prospective comparison and possibly randomized trials between double-unit CB and adult unrelated donor transplantation.

CORD BLOOD UNIT SELECTION

Efficient search and selection of CB units requires decision making as to what banks to consider and what factors to prioritize in unit selection. The unit selection algorithm currently used at MSKCC is shown in Fig. 108-8.[61] Primary unit selection criteria are based on the prethaw cryopreserved TNC/kg, the unit-recipient HLA match

Table 108-3 Comparison of Double-Unit Cord Blood Transplantation With Adult Donor HSC Transplantation

Reference	Graft/Patients (*n*)	Median Age, Years (range)	Conditioning (Patients, *n*)	Neutrophil Engraftment or Median Days to ANC (range)	II to IV Acute	Chronic GVHD	TRM	Survival (PFS or DFS)

(4-6/6 of HLA-A, -B antigen and -DRB1 allele), and the bank of origin based on the authors' experience with the bank and their accreditation. Other factors such as the availability of confirmatory HLA typing on an attached segment and the completeness of maternal infectious disease marker and hemoglobinopathy testing are also taken into account.

The exact threshold for acceptable TNC/kg has yet to be established and varies with HLA match. For example, the 2010 NYBC analysis of single-unit CBT demonstrated that recipients of units with a 6/6 HLA match had the best transplantation outcomes regardless of the cryopreserved TNC dose. By contrast, recipients of 4/6 units required a TNC dose of 5.0×10^7/kg or greater to achieve similar TRM and DFS to that of recipients of 5/6 units with TNC of $2.5\text{-}4.9 \times 10^7$/kg.[17] Although the numbers of DCBT recipients available do not yet permit such analysis, it is likely that similar principles will be found associated with the engrafting unit in DBCT recipients. Indeed, Avery et al[40] have reported that a higher infused TNC and $CD34^+$ cell dose in the engrafting unit of a double-unit pair was strongly associated with the speed and success of neutrophil engraftment. However, because it is not currently possible to predict which unit will predominate at the time of double-unit graft selection, a minimum threshold for each unit of a double-unit graft is needed. Based on the Avery et al analysis, a minimum TNC dose threshold of at least 2.0×10^7/kg is currently recommended in DCBT.

Recent analyses have highlighted new factors to be considered in unit selection. The 2009 NYBC analysis evaluated the impact of fetal exposure to noninherited maternal antigens (NIMAs) on the outcome of CBT.[62] The 79 single-unit CBT recipients that had an HLA-mismatched antigen that was identical to a donor NIMA engrafted earlier and had lower TRM and overall mortality. There was also a lower tendency toward relapse among patients with myeloid malignancies. Subsequently, in 2011, the NYBC analyzed the effect of HLA-mismatch vector in 1202 single-unit CBT recipients.[63] They identified 98 donor–recipient pairs with only unidirectional mismatches (58 in the graft-versus-host direction and 40 in the rejection direction). The graft-versus-host vector group had faster engraftment and decreased TRM and overall mortality compared with the one-bidirectional mismatch reference group, but recipients of rejection only mismatched units had slower engraftment, a higher incidence of graft failure, and higher relapse rates. Also in 2011, Eapen et al[25] reported that HLA-C matching is important in addition to HLA-A, -B, and -DRB1, although how to balance this against TNC dose needs to be further investigated. Finally, the potential importance of antigens in the patients that are shared with inherited paternal antigens (IPAs) in the CB donor that could be a target for maternal T cells has recently been reported as a potential mechanism of reduced relapse after CBT.[64]

The findings concerning the importance of HLA-mismatch vector and HLA-C can be immediately incorporated into CB unit selection algorithms, but incorporation of NIMA and IPA will require banks to provide maternal typing. In addition, although the best available CB unit or units are selected as the graft, it is important to identify and reserve at least one backup unit in the event of problems with unit shipment, mislabeling, problems with thaw, or graft failure.[65,66a,66b] At MSKCC, the authors select at least one domestic unit as backup to ensure the timely infusion of an optimal CB product.

NOVEL STRATEGIES TO ENHANCE ENGRAFTMENT

One of the main limitations of myeloablative CBT is the delayed time to neutrophil recovery compared with the transplantation of related and unrelated donor peripheral blood HSCs. This leads to prolonged hospitalization, higher rates of early infectious complications, and increased early TRM. Thus, strategies to enhance engraftment are of great interest. Studies investigating the infusion of multiple small CB units have not enhanced engraftment.[67,68] Results of direct intra-BM injection of CB have been mixed[69,70] with a study at the University of Minnesota study being abandoned for futility. New approaches focusing on enhancing engraftment are summarized in Table 108-4.

The Spanish group of Fernandez et al[71] evaluated the co-infusion of $CD34^+$ cells from a related haploidentical donor with a single-unit CBT as a "bridge" strategy to shorten the period of posttransplant neutropenia. Subsequently, these investigators updated their

Table 108-4 Potential Strategies to Enhance Cord Blood Engraftment

Strategy	Reference	Protocol	Patients (*n*)	Median Age (yr)	Neutrophil Engraftment	Platelet Engraftment (≥20,000/mm³)	Outcomes
Co-infusion of HSC	Bautista et al[72]	Single CB units + co-infusion of TCD HSC from haploidentical or third-party donors	55	34	96%; median ANC, 10 days (9-36)	78%; median time, 32 days (13-98)	DFS 47% and OS 56% at 5 years

experience using mobilized peripheral blood HSCs from either a haploidentical or an unmatched third-party donor to support single-unit CBT.[72] This series included 55 patients with high-risk hematologic malignancies. The median time to neutrophil recovery was 10 days, and there was a high incidence of neutrophil engraftment of 96%; the median time to platelets greater than 20,000/mm³ was 32 days with an incidence of 78%. The cumulative incidence of full CB chimerism was 91% and took a median of 44 days. Grade II to IV acute GVHD developed in 10 patients and grade III to IV acute GVHD in 6 patients. Twenty-two patients died (three relapse, six organ failure, four GVHD, eight infection, one graft failure). The 5-year overall survival and DFS were 56% and 47%, respectively. The van Besien group recently reported similar findings that included 45 patients with hematologic malignancies (47% had refractory or untreated relapse) who received reduced-intensity conditioning followed by transplantation of a single CB unit and CD34⁺ cells from a haploidentical donor.[73] Rapid engraftment was obtained with cumulative incidences for neutrophils and platelets (>20,000/mm³) of 95% at day 50 and 83% at day 100, respectively, with a median time to recovery of 11 days for neutrophils and 19 days for platelets. However, the percentage of host-derived hematopoiesis was 5% by day 180, and four patients had graft failure (two primary and two secondary). The cumulative incidence of grade II to IV acute GVHD was 25%, and the 1-year overall survival and PFS rates were 55% and 42%, respectively.

Cord blood expansion is another approach to enhance neutrophil recovery. Peled et al[74,75] have cultured of $CD34^+38^-$ CB HSCs with a copper chelator tetraethylenepentamide (TEPA) given that cellular copper has been found implicated in the regulation and differentiation of HSC. The group of Shpall conducted a phase I/II clinical trial in which a portion of a single CB unit was cultured with TEPA and cytokines for 21 days and was co-infused to the patient with the unmanipulated portion.[76] The fold expansion for TNC and CD34⁺ were 219 and six, respectively. This methodology was proven to be safe, but time to neutrophil engraftment was not improved (median absolute neutrophil count was 30 days and median to platelets >20,000/mm³ was 48 days).

Delaney et al[44] studied a double-unit CB strategy in which CD34⁺ CB progenitors were expanded using a notch-ligand based culture that resulted in an average expansion of 562- and 164-fold for TNC and CD34⁺ cells, respectively. Thus, the average infused CD34⁺ cell dose from the expanded unit was 6×10^6/kg. The expansion was initiated 16 days before transplantation, and cultures were harvested and co-infused after the infusion of an unmanipulated CB unit. Ten patients with high-risk hematologic malignancies were transplanted. The median CD34⁺ cell dose from the manipulated unit was significantly higher than the unmanipulated CB units (6×10^6/kg vs. 0.24×10^6/kg) with a fold expansion for TNC and CD34⁺ of 660 and 160, respectively. An accelerated myeloid engraftment was observed with a median neutrophil recovery in nine of 10 evaluable patients of 16 days (range, 7-34), although one patient had primary graft rejection. The seven surviving patients, however, had sustained donor engraftment mediated exclusively by the unmanipulated unit likely caused by the depletion of T cells in the manipulated unit.

de Lima et al[77] have reported an ex vivo expansion approach of CD34⁺ cells using a mesenchymal stromal cell–based culture derived from either third-party haploidentical family member BM or universal donors. The median expansion for TNC was 14-fold and for CD34⁺ was 40-fold. This method resulted in successful engraftment in 31 of 32 patients with significant shortening of neutropenia (median, 15 days) and platelets engrafted at a median of 40 days. Eleven patients survived for an overall survival of 40% at 1 year. The incidences of grade II to IV and III to IV acute GVHD were 50% and 16%, respectively. Preclinical data with aryl hydrocarbon

receptor antagonists[78] and novel cytokines[79,80] with enhanced HSC expansion capacity are promising approaches that are currently under investigation.

Another method to improve engraftment is to enhance stem cell homing to the BM niche. The Broxmeyer group have reported that endogenous CD26 expression negatively regulates the homing and engraftment of stem cells.[81,82] Campbell et al[81] evaluated pretreated purified $CD34^+$ human CB cells with a CD26 peptidase inhibitor (Ditropin A) and found a significant enhanced engraftment in NOD/SCID mice. Christopherson et al[83] demonstrated that transplantation of either $CD34^+$ or lineage depleted human CB cells in NOD/SCID/B2m-^{null} mice after treatment with a CD26 inhibitor was associated with a significant improvement in the engraftment of long-term repopulating. Moreover, Hidalgo et al[84] found a defect in CB homing that was likely associated to reduced α-1,3-fucosyltransferase expression and activity in CB $CD34^+$ cells, decreasing their ability to bind to P- and E-selectins expressed by the BM vasculature. Subsequently, Robinson et al[85] demonstrated that human $CD34^+$ CB cells fucosylated using a recombinant fucosyl transferase in a murine model exhibited improved engraftment. Cutler et al[86] are investigating the ex vivo treatment of human CB cells with 16,16-dimethyl prostaglandin E2 (FT 1050) as a method to enhance engraftment by improved homing. One advantage of this method is that it only requires 1 to 2 hours of incubation before infusion. An early phase clinical trial is being conducted in adults with hematologic malignancies with 1 of 2 units of a double-unit graft being incubated with the agent.

ADOPTIVE IMMUNOTHERAPY

Cord blood transplantation offers a platform for the investigation of novel immunotherapy strategies to treat viral infections, enhance antitumor responses, and prevent GVHD (Table 108-5). Sun et al[87] have reported the generation of $CD4^+$ EBV-specific cytotoxic lymphocytes from CB, and Park et al[88] have generated CMV pp65-specific T cells from CB. The Bollard group has generated multivirus-specific T cells from CB lymphocytes to prevent and treat CMV, EBV, and adenovirus.[89,90] The efficacy of these cells is currently being evaluated in a phase I trial. The O'Reilly group at MSKCC has investigated the alternative approach of using third-party EBV-specific cytotoxic T lymphocytes to successfully treat EBV associated posttransplant lymphoma in two CBT recipients who failed tapering of immunosuppression and rituximab therapy.[91]

Cord blood transplantation is also being used as a platform to enhance antitumor responses. CB NK cells have demonstrated in vitro and in vivo antileukemic effects. The enhancement of NK cells cytolytic activity by IL-2 exposure in a murine model has been reported by the Xing group.[92] Micklethwaite et al[93] have generated T cells from CB cells with both antiviral activity against CMV, EBV, and adenovirus (multivirus specific cytotoxic lymphocytes) and antileukemic activity by retroviral transduction of chimeric antigen receptors (CAR) for the CD19 molecule expressed in B-cell acute lymphoblastic leukemia. The efficacy of this approach has been demonstrated in vitro, and results of clinical application are awaited with great interest. Brunstein et al[45] have reported the results of a phase I clinical trial of CB derived ex vivo expanded Tregs. Twenty-three nonmyeloablative CBT recipients received Treg infusion(s) manufactured from a third-party CB donor in addition to a double-unit CB graft. This was well tolerated without toxicities. The incidence of grade II to IV aGVHD of 43% was lower than the 61% in the historical control participants ($P = .05$).

Table 108-5 Cellular Therapeutic Strategies to Mitigate Viral Infections, Relapse, and Graft-Versus-Host Disease After Cord Blood Transplantation

Target	Strategy	Results
Antiviral	Multivirus specific CTLs (CMV, EBV, adenovirus)[90]	Lysed antigen-pulsed and virus infected targets
	Third-party EBV-specific CTLs[91]	2 EBV PTLD patients achieved durable CR
Antitumor	IL-2 expansion of CB NK cells[92]	Cytolytic effect in vitro and in vivo against leukemia cells
Antitumor and antiviral	CB derived CTLs against CD19 and viruses (CMV, EBV, adenovirus)[93]	In vitro antileukemic and antiviral effect
GVHD prevention	Infusion of ex vivo expanded CB Treg[45]	23 patients accrued; aGVHD incidence decreased without increase in relapse

aGVHD, Acute graft-versus-host disease; *CB,* cord blood; *CBT,* cord blood transplantation; *CMV,* cytomegalovirus; *CR,* complete remission; *CTL,* cytotoxic T cell lymphocyte; *EBV,* Epstein-Barr virus; *GVHD,* graft-versus-host disease; *IL-2,* interleukin-2; *NK,* natural killer; *PTLD,* posttransplant lymphoproliferative disease; *Treg,* regulatory T cell.

FUTURE DIRECTIONS

Cord blood is a promising alternative HSC source for use in the transplantation of patients with high-risk hematologic malignancies. CBT extends transplant access to patients from ethnic and racial minorities and those in need of urgent transplantation. Furthermore, survival after CBT has greatly improved because of larger CB inventory; possibly better unit quality; and improved conditioning regimens, grafts, and supportive care. Single-unit CBT has been shown to be comparable to unrelated donor transplantation in children,[21] and DCBT has had comparable DFS to the transplantation of adult donor HSC.[48,59,60] CBT should be considered as an immediate alternative in patients with high-risk hematologic malignancies who are candidates for allogeneic HSC transplantation but lack a suitable related donor.

CHAPTER 109

GRAFT-VERSUS-HOST DISEASE AND GRAFT-VERSUS-LEUKEMIA RESPONSES

Pavan Reddy and James L.M. Ferrara

The ability of allogeneic hematopoietic cell transplantation (HCT) to cure certain hematologic malignancies is widely recognized. An important therapeutic aspect of HCT in eradicating malignant cells is the graft-versus-leukemia (GVL) effect. The importance of the GVL effect in allogeneic HCT has been recognized since the earliest experiments in stem cell transplantation. Forty years ago Barnes and colleagues noted that leukemic mice treated with a subtherapeutic dose of radiation and a syngeneic (identical twin) graft transplant were more likely to relapse than mice given an allogeneic stem cell transplant.[1,2] They hypothesized that the allogeneic graft contained cells with immune reactivity necessary for eradicating residual leukemia cells. They also noted that recipients of allogeneic grafts, though less likely to relapse, died of a "wasting syndrome" now recognized as graft-versus-host disease (GVHD). Thus in addition to describing GVL, these experiments highlighted for the first time the intricate relationship between GVL and GVHD. Since these early experiments, both GVHD and the GVL effect have been studied extensively.[3] This chapter reviews the pathophysiology, clinical features, and treatment of GVHD and summarizes current understanding of the relationships between GVHD and the GVL effect.

GRAFT-VERSUS-HOST DISEASE: CLINICAL AND PATHOLOGIC ASPECTS

Ten years after the work of Barnes and Loutit, Billingham formulated the requirements for the development of GVHD: the graft must contain immunologically competent cells, the recipient must express tissue antigens that are not present in the transplant donor, and the recipient must be incapable of mounting an effective response to destroy the transplanted cells.[4] According to these criteria, GVHD can develop in various clinical settings when tissues containing immunocompetent cells (blood products, bone marrow, and some solid organs) are transferred between persons. The most common setting for the development of GVHD is following allogeneic HCT; without prophylactic immunosuppression, most allogeneic HCTs will be complicated by GVHD. GVHD occurs secondary to mismatches between histocompatibility antigens between the donor and recipient. Matching of the major histocompatibility complex (MHC) antigens hastens engraftment and reduces the severity of GVHD.[5] The MHC contains the genes that encode tissue antigens and were first identified functionally in murine models as transplantation antigens responsible for rejection of tissue grafts. In humans, the MHC region lies on the short arm of chromosome 6 and is called the HLA (human leukocyte antigen) region.[6] The HLA region includes many genes, not all of which are involved in immune activation. It is divided into two classes, class I and class II, each containing numerous gene loci that encode a large number of polymorphic alleles. MHC class I molecules are involved in the presentation of peptides to $CD8^+$ T cells, and class II molecules present peptides to $CD4^+$ T cells.[6]

Each MHC antigen is composed of two polypeptide chains. Class I antigens are made up of a heavy chain that contains the polymorphic regions and the nonpolymorphic light chain, $beta_2$ microglobulin. The class IHLA antigens include HLA A, B, and C antigens. These are expressed on almost all cells of the body at varying densities.[6,7] Both chains of class II antigens contain polymorphic regions and are encoded in the MHC. The class II antigens are further divided into DR, DQ, and DP antigens. Class II antigens are expressed on B cells, dendritic cells, and monocytes, and their expression can be induced on many other cell types following inflammation or injury.[6,8] The determination of HLA types has become much more accurate with molecular techniques that replace earlier serologic or cellular methods. In patients whose ancestry involves extensive interracial mixing, the chances of identifying an HLA identical donor are diminished.[9]

Despite HLA identity between a patient and donor, substantial numbers of patients still develop GVHD because of differences in minor histocompatibility antigens that lie outside the HLA loci. Most minor antigens are expressed on the cell surface as degraded peptides bound to specific HLA molecules, but the precise elucidation of many human minor antigens is yet to be accomplished.[10] In the United States, the average patient has a 25% chance of having an HLA match within his or her immediate family.[9] Patients who lack an HLA-identical family member donor must seek unrelated donor volunteers or cord blood donations.

Acute Graft-Versus-Host Disease

Acute GVHD can occur within days (in recipients who are not HLA-matched with the donor or in patients not given any prophylaxis) or as late as 2 months after transplantation. The incidence ranges from less than 10% to more than 80%, depending on the degree of histoincompatibility between donor and recipient, the number of T cells in the graft, the patient's age, and the GVHD prophylactic regimen.[11] The principal target organs include the immune system, skin, liver, and intestine. GVHD occurs first and most commonly in the skin as a pruritic maculopapular rash, often involving the palms, soles, and ears; it can progress to total-body erythroderma, with bullae formation, rupture along the epidermal-dermal border, and desquamation in severe cases.[11] Gastrointestinal (GI) and liver manifestations often appear later and rarely represent the first and only findings. Intestinal symptoms include anorexia, nausea, diarrhea (sometimes bloody), abdominal pain, and paralytic ileus.[11] Liver dysfunction includes hyperbilirubinemia and increased serum alkaline phosphatase and aminotransferase values. Coagulation studies may become abnormal, and hepatic failure with ascites and encephalopathy may develop in severe cases.[11-13] Hepatic GVHD can be distinguished from hepatic venoocclusive disease by weight gain or pain in the right upper quadrant in the latter.[13] Acute GVHD also results in the delayed recovery of immunocompetence.[11] The clinical result is profound immunodeficiency and susceptibility to infections, often further accentuated by the immunosuppressive agents used to treat GVHD.[11]

Pathologically, the sine qua non of acute GVHD is selective epithelial damage of target organs.[14,15] The epidermis and hair follicles are damaged and sometimes destroyed. Small bile ducts are profoundly affected, with segmental disruption. The destruction of intestinal crypts results in mucosal ulcerations that may be either patchy or diffuse. Other epithelial surfaces, such as the conjunctivae, vagina, and esophagus, are less commonly involved. A peculiarity of GVHD histology is the frequent paucity of mononuclear cell infiltrates;

however, as the disease progresses, the inflammatory component may be substantial. Recent studies have identified inflammatory cytokines as soluble mediators of GVHD and have suggested that direct contact between target cells and lymphocytes may not be required for target cell destruction (see following sections). GVHD lesions are not evenly distributed in the target tissues. In the skin, damage is prominent at the tip of rete ridges; in the intestine, at the base of the crypts; and in the liver, in the periductular epithelium. These areas contain a high proportion of stem cells, giving rise to the idea that GVHD targets may be undifferentiated epithelial cells with primitive surface antigens.[16]

The histologic severity of a given lesion is at best semiquantitative, and consequently the severity of pathologic findings is not used in the grading of GVHD. Because it is often difficult to obtain an adequate tissue biopsy, the physician is left to use clinical judgment. Even on histology, it can be very difficult to distinguish GVHD from other post–bone marrow transplantation (BMT) complications such as drug eruptions or infectious complications.

A recent multicenter phase III trial used an independent committee to assess the presence and severity of GVHD. The incidence of GVHD as determined by investigators was substantially higher than the review committee could confirm.[17] Nevertheless, for an experienced clinician a combination of physical and laboratory findings in the appropriate context provides a working diagnosis of GVHD that is satisfactory to produce a meaningful prognostic scale based on clinical grading system.[18] Standard grading systems generally include clinical changes in the skin, GI tract, liver, and performance status (Table 109-1).[19] Although the severity of GVHD is sometimes difficult to quantify, the overall grade correlates with disease outcome. Whereas mild GVHD (grade I or II) is associated with little morbidity and almost no mortality, higher grades are associated with significantly decreased survival.[19,20] With grade IV GVHD, the mortality rate is almost 100%.[20]

Clinical Features of Acute GVHD

The clinical features, staging, and grading of acute GVHD are summarized in Tables 109-1 and 109-2. In a comprehensive review of patients receiving therapy for acute GVHD, Martin and colleagues[21] found that 81% had skin involvement, 54% had GI involvement, and 50% had liver involvement at the initiation of therapy. After high-intensity (conventional) conditioning, acute GVHD generally occurs within 14-35 days of stem cell infusion. The time of onset may depend on the degree of histocompatibility, the number of donor T cells infused and the prophylactic regimen for GVHD. A "hyperacute" form of GVHD may occur in patients with severe HLA mismatches and in patients who receive T-cell replete transplants without or with inadequate in vivo GVHD prophylaxis.[22] It is, however, important to note that this hyperacute form is pathophysiologically distinct from the hyperacute rejection after solid organ allografting. This form of GVHD is manifested by fever, generalized erythroderma and desquamation, and often edema. It typically occurs about 1 week after stem cell infusion and may be rapidly fatal. In patients receiving more conventional (in vivo) GVHD prophylaxis, such as a combination of cyclosporine (CSP) and methotrexate, the median onset of GVHD is typically 21 to 25 days after transplantation; however, after in vitro T-cell depletion of the graft the onset may be much later.[22] Thus the findings of rash and diarrhea by 1 week after transplantation would very likely be hyperacute manifestations of GVHD if minimal or ineffective prophylaxis were administered; the same kinetics would be very unlikely with the use of calcineurin inhibitors or in vitro T-cell depletion of the stem cell inoculum. A less ominous syndrome of fever, rash, and fluid retention occurring in the first 1 to 2 weeks after stem cell infusion is the "engraftment syndrome." These manifestations may be seen with either allogeneic or autologous transplantation. Although the pathophysiology is poorly understood, it is thought to be due to a wave of cytokine production as the graft starts to recover. This is related to, but distinct from, the "cytokine storm"[23] that is thought to contribute to acute GVHD in that there is no concomitant T cell–mediated attack. This syndrome responds immediately to steroids in most patients, and it typically presents earlier than acute GVHD.[16] In autologous transplantation the differential diagnosis is of little relevance, but in allogeneic transplant recipients it must be distinguished from the hyperacute manifestations of GVHD. A prompt response to steroids would argue in favor of an engraftment syndrome, although some patients with GVHD will also respond.

Skin is the most commonly affected organ (Fig. 109-1). In patients receiving transplants after myeloablative conditioning, the skin is usually the first organ involved, and GVHD often coincides with engraftment. However, the presentation of GVHD is more varied following nonmyeloablative transplants or donor lymphocyte infusions.[24] The characteristic maculopapular rash can spread throughout the rest of the body but usually spares the scalp; it is often described as feeling like a sunburn, tight or pruritic. In severe cases the skin may blister and ulcerate.[25] Histologic confirmation is critical to rule out drug reactions, viral infections, etc. Apoptosis at the base of dermal crypts is characteristic. Other features include dyskeratosis, exocytosis of lymphocytes, satellite lymphocytes adjacent to dyskeratotic epidermal keratinocytes, and dermal perivascular lymphocytic infiltration.[26]

Gastrointestinal tract involvement of GVHD may present as nausea, vomiting, anorexia, diarrhea, and/or abdominal pain.[27] It is a panintestinal process, often with differences in severity between the upper and lower GI tracts. Gastric involvement gives rise to

Table 109-1 Clinical Manifestations and Staging of Acute Graft-Versus-Host Disease

Organ	Clinical Manifestations	Staging
Skin	Erythematous, maculopapular rash involving palms and soles; may become confluent Severe disease: bullae	Stage 1: <25% rash Stage 2: 25% to 50% rash Stage 3: generalized erythroderma Stage 4: bullae
Liver	Painless jaundice with conjugated hyperbilirubinemia and increased alkaline phosphatase	Stage 1: bili 2 to 3 mg/dL Stage 2: bili 3.1 to 6 mg/dL Stage 3: bili 6.1 to 15 mg/dL Stage 4: bili >15 mg/dL
Gastrointestinal tract	Upper: nausea, vomiting, anorexia Lower: diarrhea, abdominal cramps, distension, ileus, bleeding	Stage 1: diarrhea >500 mL/day Stage 2: diarrhea >1000 mL/day Stage 3: diarrhea >1500 mL/day Stage 4: ileus, bleeding

Table 109-2 Glucksberg Criteria for Staging of Acute Graft-Versus-Host Disease*

Overall Grade	Skin	Liver		Gut
I	1-2	0		0
II	1-3	1	and/or	1
III	2-3	2-4	and/or	2-3
IV	2-4	2-4	and/or	2-4

*See Table 109-1 for individual organ staging. Traditionally, individual organs are staged without regard to attribution. The overall grade of GVHD, however, reflects the actual extent of GVHD. To achieve each overall grade, skin disease plus liver and/or gut involvement are required.

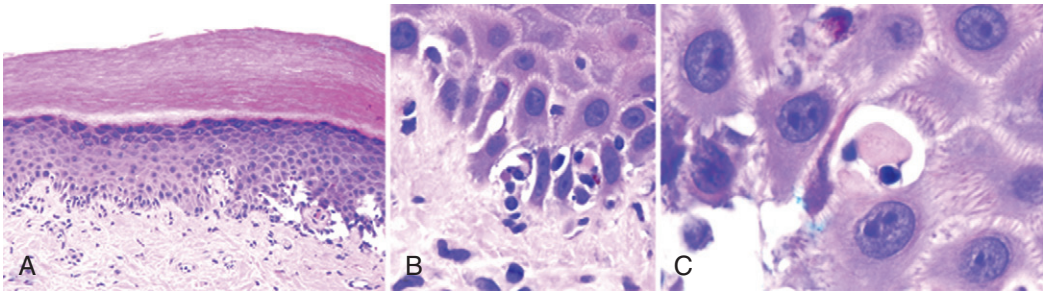

Figure 109-1 GRAFT-VERSUS-HOST DISEASE, SKIN BIOPSY. This 40-year-old man with a history of relapsed Hodgkin lymphoma was status-postallogeneic stem cell transplant with donor lymphocyte infusion. He developed painful oral ulcers and a macular-papular rash on the arms, hand, and chest. The skin biopsy is from the palmar surface of the hand **(A).** It shows a scant lymphoid infiltrate in the dermis with a developing subepithelial blister *(right)*. There is basal vacuolar change **(B)** with single lymphocytes in the epithelium, as well as apoptotic keratinocyte accompanied by lymphocytes **(B,** and detail, **C).** *(Courtesy Vesna Petronic-Rosic and Mark Racz, University of Chicago.)*

postprandial vomiting that is not always preceded by nausea. Although gastroparesis is seen after bone marrow transplant, it is usually not associated with GVHD. The diarrhea of GVHD is secretory; significant GI blood loss may occur as a result of mucosal ulceration and is associated with a poor prognosis.[28] In advanced disease, diffuse, severe abdominal pain and distension is accompanied by voluminous diarrhea (>2 liters/day).[20,29]

Radiologic findings of the GI tract include luminal dilatation with thickening of the wall of the small bowel and air/fluid levels suggestive of an ileus on abdominal flat plates or small bowel series. Abdominal computed tomography may show the "ribbon" sign of diffuse thickening of the small bowel wall.[25] Little correlation exists between the extent of disease and the appearance of mucosa on endoscopy, but mucosal sloughing is pathognomonic for severe disease.[30] Nevertheless, some studies have shown that antral biopsies correlate well with the severity of GVHD in the duodenum and in the colon even when the presenting symptom is diarrhea.[30] Histologic analysis of tissue is imperative to establish the diagnosis. The histologic features of GI GVHD are the presence of apoptotic bodies in the base of crypts, crypt abscesses, crypt loss, and flattening of the surface epithelium.[29,31]

Liver function test abnormalities are common after bone marrow transplant and occur secondary to venoocclusive disease, drug toxicity, viral infection, sepsis, iron overload, and other causes of extrahepatic biliary obstruction.[13] The exact incidence of hepatic GVHD is probably underreported because many patients do not undergo liver biopsies. The development of jaundice or an increase in the alkaline phosphatase and bilirubin may be the initial features of acute GVHD of the liver. The histologic features of hepatic GVHD are endothelialitis, lymphocytic infiltration of the portal areas, pericholangitis, and bile duct destruction and loss.[20,32]

Other Organs

Whether GVHD affects organs other than the classic triad of skin, liver, and gut has remained a matter of debate. However, numerous reports suggest additional organ manifestations. The most likely candidate is the lung. Lung toxicity, including interstitial pneumonitis and diffuse alveolar hemorrhage, may occur in 20% to 60% of allogeneic transplant recipients but in fewer autologous transplant recipients. Causes of pulmonary damage other than GVHD include engraftment syndrome (see later), infection, radiation pneumonitis, and chemotherapy-related toxicity (e.g., methotrexate, busulfan).[22,33] At least one retrospective analysis failed to link severe pulmonary complications to clinical acute GVHD per se.[34] The mortality due to pneumonia increases with the severity of GVHD, but this association does not necessarily imply that GVHD, as opposed to immunosuppression given for therapy, is causative.[22] A particular histopathologic syndrome of lymphocytic bronchitis has been attributed directly to GVHD,[33] although this association has not been confirmed by others.

Despite the fact that kidneys and heart can be targets for allogeneic damage as evidenced by their rejection after renal and cardiac transplants respectively, there is no convincing evidence for direct renal or cardiac damage from acute GVHD that is not secondary to drugs or infection. Similarly, neurologic complications are also common after transplantation but most can be attributed to drug toxicity, infection, or vascular insults.

Differential Diagnosis

Acute GVHD ought to be distinguished from any process that causes a constellation of fever, erythematous skin rash with or without low-pressure, and pulmonary edema that may occur during neutrophil recovery. This picture may reflect the dysregulated production of inflammatory cytokines and cellular responses to these molecules, and has been termed engraftment or capillary leak syndrome.[35,36] The picture is most clearly recognized after autologous transplantation where, theoretically, GVHD should not occur. In allogeneic transplant recipients, distinction from acute GVHD is difficult. This engraftment syndrome is thought to reflect cellular and cytokine activities during early recovery of (donor-derived) blood cell counts and/or homeostatic proliferation of lymphocytes, but a precise delineation of the offending cells and mechanisms has not been accomplished. Engraftment syndromes may be associated with increased mortality, primarily from pulmonary failure but also (other) multiorgan dysfunction. Corticosteroid therapy may be effective particularly for the treatment of pulmonary manifestations.[37] The differential diagnosis of skin rashes, diarrhea, and liver function abnormalities can be difficult to resolve. Skin rashes may reflect delayed reactions to the conditioning regimen, antibiotics, or infections; furthermore, histopathologic skin changes consistent with acute GVHD can be mimicked by chemoradiotherapy and drug reactions.[22,38] Diarrhea can be a consequence of TBI, viral infection (especially with CMV and other herpes viruses), parasitic infection, *C. difficile* infection, nonspecific gastritis, narcotic withdrawal, and drug reactions—all of which mimic GVHD of the gut. Liver dysfunction can be due to parenteral nutrition, venoocclusive disease, and viral- or drug-induced hepatitis.

Genetic Basis of Graft-Versus-Host Disease

The graft-versus-host (GVH) reaction was first noted when irradiated mice were infused with allogeneic marrow and spleen cells.[39] Although mice recovered from radiation-induced injury and marrow aplasia, they subsequently died with "secondary disease,"[39] a phenomenon subsequently recognized as acute GVHD. Three requirements for the development of GVHD were formulated by Billingham.[4] First, the graft must contain immunologically competent cells, now recognized as mature T cells. In both experimental and clinical allogeneic HCT,

the severity of GVHD correlates with the number of donor T cells transfused.[40,41] The precise nature of these cells and the mechanisms they use are now understood in greater detail (discussed later). Second, the recipient must be incapable of rejecting the transplanted cells (i.e., immunocompromised). A patient with a normal immune system will usually reject cells from a foreign donor. In an allogeneic transplant setting, the recipient is typically immunosuppressed by chemo- and/or radiotherapy before the hematopoietic cell infusion.[42] Third, the recipient must express tissue antigens that are not present in the transplant donor. Thus Billingham's third postulate stipulates that the GVH reaction occurs when donor immune cells recognize disparate host antigens.[4] These differences are governed by the genetic polymorphisms of the HLA system and the non-HLA systems.[42]

HLA Matching

Alloreactive T-cell antigen recognition is characterized by whether the presenting major histocompatibility molecule is matched or mismatched.[43-45] In humans, the MHC is governed by the HLA antigens that are encoded by the MHC gene complex on the short arm of chromosome 6 and can be categorized as class I, II, and III. Class I antigens (HLA-A, B, and C) are expressed on almost all cells of the body.[46] Class II antigens (DR, DQ, and DP) are primarily expressed on hematopoietic cells, although their expression can also be induced on other cell types following inflammation.[46] The incidence of acute GVHD is directly related to the degree of MHC mismatch.[42] The role of HLA mismatching in CBT is more difficult to analyze compared with unrelated donor HCT, because allele typing of CB units for HLA-A, B, C, DRB1, and DQB1 is not routinely performed.[47] Nonetheless, the total number of HLA disparities between the recipient and the CB unit has been shown to correlate with risk for acute GVHD as the frequency of severe acute GVHD is lower in patients transplanted with HLA-matched (6/6) CB units.[47-49]

Minor Histocompatibility Antigens

In the MHC-matched context, as is the case with most clinical allogeneic transplants, donor T cells recognize MHC-bound peptides derived from the protein products of polymorphic genes (minor histocompatibility antigens [MiHAs]) that are present in the host but not in the donor.[10,50-55] Substantial numbers (40%) of patients will develop acute GVHD despite receiving HLA-identical grafts as well as optimal postgrafting immune suppression.[10,42,56] Minor histocompatibility antigens are widely expressed but can differ in their tissue expression.[51,56] This might be one of the reasons for the unique target organ involvement in GVHD. A preponderance of MiHAs, such as HA-1 and HA-2, are expressed on hematopoietic cells, which might account for making the host immune system a primary target for the GVH response and explain the critical role of direct presentation by professional recipient antigen-presenting cells (APCs) in causing antitumor and GVHD responses.[57] By contrast, other MiHAs, such as H-Y and HA-3, are expressed ubiquitously.[56] Minor histocompatibility antigens are not equal in their ability to induce lethal GVHD and instead show hierarchic immunodominance.[58,59] Furthermore, the difference in single immunodominant MiHAs alone is not insufficient for causing GVHD in murine models, although T cells targeting single MiHAs can induce tissue damage in a skin explant model.[60,61] However, the role of specific and immunodominant MiHAs that are relevant in clinical GVHD has not been systematically evaluated in large groups of patients.[62]

Other Non-HLA Genes

Genetic polymorphisms in several non-HLA genes such as in killer-cell immunoglobulin-like receptors (KIRs), cytokines and nucleotide-binding oligomerization domain containing 2 (NOD2) genes have recently been shown to modulate the severity and incidence of GVHD.

KIRs on natural killer (NK) cells that bind to the HLA class I gene products are encoded on chromosome 19. Polymorphisms in the transmembrane and cytoplasmic domains of KIRs govern whether the receptor has inhibitory (such as KIR2DL1, -2DL2, -2DL3, and -3DL1) or activating potential. Two competing models have been proposed for HLA-KIR allorecognition by donor NK cells following allogeneic HCT: the "mismatched ligand" and the "missing ligand" models.[5,63-66] Both models are supported by several clinical observations, albeit in patients receiving very different transplant and immunosuppressive regimens (see Chapters 20 and 102).[64,67-69]

Proinflammatory cytokines, involved in the classic cytokine storm of GVHD (discussed later), cause pathologic damage to target organs, such as the skin, liver, and gastrointestinal tract.[23] Several cytokine gene polymorphisms, in recipients as well as donors, have been implicated. Specifically, tumor necrosis factor (TNF) polymorphisms (TNFd3/d3 in the recipient, TNF863 and TNF857 in donors and/or recipients and TNFd4, TNF-α-1031C, and TNFRII-196R in the donors) have been associated with an increased risk for acute GVHD and TRM.[70,71] The three common haplotypes of the interleukin (IL)-10 gene promoter region in recipients, representing high, intermediate, and low production of IL-10, have been associated with severity of acute GVHD following HLA-matched sibling donor allogeneic HCT.[72] By contrast, smaller studies have found neither IL-10 nor TNF-α polymorphisms to be associated with GVHD following HLA-mismatched CBT.[71,73] Interferon-gamma (IFN-γ) polymorphisms of the 2/2 genotype (high IFN-γ production) and 3/3 genotype (low IFN-γ) have been associated with decreased or increased acute GVHD, respectively.[71,74]

NOD2/caspase-activating recruitment domain 15 (CARD15) gene polymorphisms in both the donors and recipients were recently shown to have a striking association between GI GVHD and overall mortality following related and unrelated donor allogeneic HCT.[75] It is likely that non-HLA gene polymorphisms play differing roles depending on the donor source (related versus unrelated), HLA disparity (matched versus mismatched), graft source (CB versus BM versus peripheral blood stem cells), and the intensity of the conditioning.

PATHOPHYSIOLOGY OF ACUTE GRAFT-VERSUS-HOST DISEASE

It is helpful to remember two important principles when considering the pathophysiology of acute GVHD. First, acute GVHD represents exaggerated but normal inflammatory responses against foreign antigens (alloantigens) that are ubiquitously expressed in a setting where they are undesirable. The donor lymphocytes that have been infused into the recipient function appropriately, given the foreign environment they encounter. Second, donor lymphocytes encounter tissues in the recipient that have been often profoundly damaged. The effects of the underlying disease, prior infections, and the intensity of conditioning regimen all result in substantial changes not only in the immune cells but also in the endothelial and epithelial cells. Thus the allogeneic donor cells rapidly encounter not simply a foreign environment, but one that has been altered to promote the activation and proliferation of inflammatory cells. Therefore the pathophysiology of acute GVHD may be considered a distortion of the normal inflammatory cellular responses that, in addition to the absolute requirement of donor T cells, involves multiple other innate and adaptive cells and mediators.[76] The development and evolution of acute GVHD can be conceptualized in three sequential phases (Fig. 109-2) to provide a unified perspective on the complex cellular interactions and inflammatory cascades that lead to acute GVHD: (1) activation of the antigen-presenting cells; (2) donor T-cell activation, differentiation, and migration; and (3) effector phase.[76] It is important to note that the following three-phase description allows for a unified perspective in understanding the biology. It is not meant to suggest, however, that all three phases are of equal importance or that GVHD occurs in a stepwise and sequential manner. The spatiotemporal relationships between the biologic processes described,

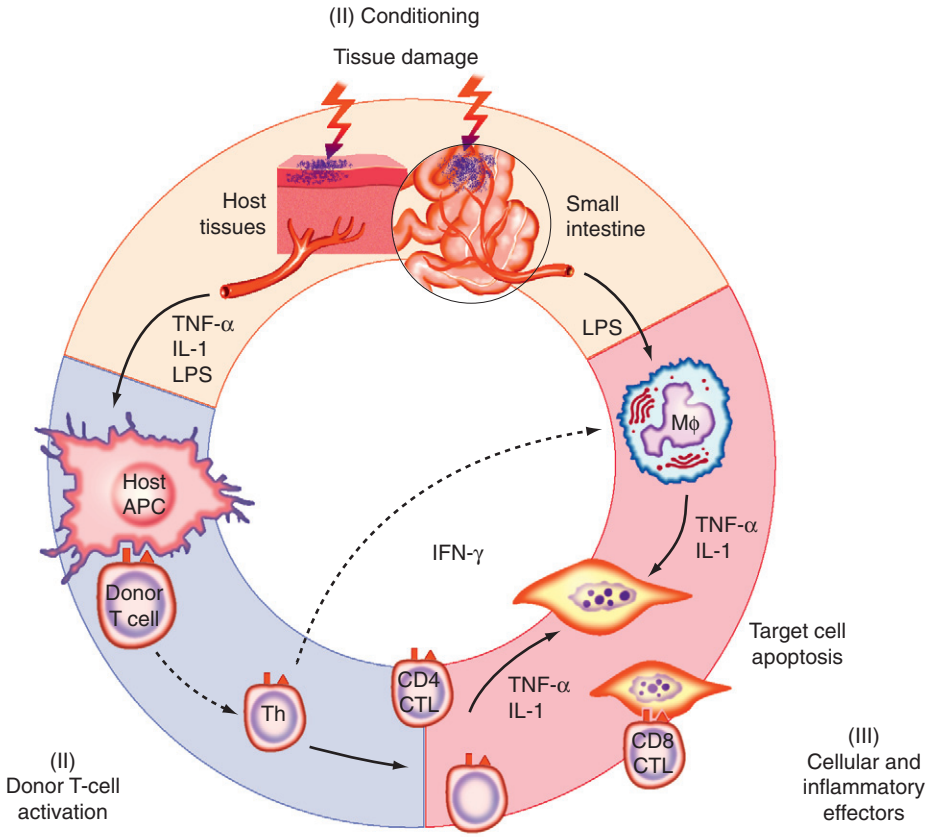

Figure 109-2 PATHOPHYSIOLOGY OF GRAFT-VERSUS-HOST DISEASE. During step 1, irradiation and chemotherapy both damage and activate host tissues, including intestinal mucosa, liver, and the skin. Activated cell hosts then secrete inflammatory cytokines (e.g., TNF-α and IL-1), which can be measured in the systemic circulation. The cytokine release has important effects on APCs of the host, including increased expression of adhesion molecules (e.g., ICAM-1, VCAM-1) and of MHC class II antigens. These changes in the APCs enhance the recognition of host MHC and/or minor H antigens by mature donor T cells. During step 2, donor T-cell activation is characterized by proliferation of GVHD T cells and secretion of the Th1 cytokines IL-2 and IFN-γ. Both of these cytokines play central roles in clonal T-cell expansion, induction of CTL and NK cell responses, and the priming of mononuclear phagocytes. In step 3, mononuclear phagocytes primed by IFN-γ are triggered by a second signal such as endotoxin (LPS) to secrete cytopathic amounts of IL-I and TNF-α. LPS can leak through the intestinal mucosa damaged by the conditioning regimen to stimulate gut-associated lymphoid tissue or Kupffer cells in the liver; LPS that penetrates the epidermis may stimulate keratinocytes, dermal fibroblasts, and macrophages to produce similar cytokines in the skin. This mechanism results in the amplification of local tissue injury and further production of inflammatory effectors such as nitric oxide, which, together with CTL and NK effectors, leads to the observed target tissue destruction in the stem cell transplant host. CTL effectors use Fas/FasL, perforin/granzyme B, and membrane-bound cytokines to lyse target cells.

depending on the context, are more likely to be chaotic and of varying intensity and relevance in the induction, severity, and maintenance of GVHD.

Phase 1: Activation of Antigen-Presenting Cells

The earliest phase of acute GVHD is initiated by the profound damage caused by the underlying disease and infections and further exacerbated by BMT conditioning regimens (which include TBI and chemotherapy) that are administered even before the infusion of donor cells.[77-81] This first step results in activation of the APCs.[8] Specifically, damaged host tissues respond with multiple changes, including the secretion of proinflammatory cytokines, such as TNF-α and IL-1, described as the "cytokine storm."[79,80,82] Such changes increase expression of adhesion molecules, costimulatory molecules, MHC antigens, and chemokines gradients that alert the residual host and the infused donor immune cells.[80] These "danger signals" activate host APCs.[83,84] Damage to the gastrointestinal tract from the conditioning is particularly important in this process because it allows for systemic translocation of immunostimulatory microbial products such as lipopolysaccharide (LPS) that further enhance the activation of host APCs, and the secondary lymphoid tissue in the GI tract is likely the initial site of interaction between activated APCs and donor T cells.[80,85,86] This scenario accords with the observation that an increased risk for GVHD is associated with intensive conditioning regimens that cause extensive injury to epithelial and endothelial surfaces with a subsequent release of inflammatory cytokines and increases in expression of cell surface adhesion molecules.[80,81] The relationship among conditioning intensity, inflammatory cytokine, and GVHD severity has been supported by elegant murine studies.[82] Furthermore, the observations from these experimental studies have led to two recent clinical innovations to reduce clinical acute GVHD: (a) reduced intensity conditioning to decrease the damage to host tissues and thus limit activation of host APC and (b) KIR mismatches between donor and recipients to eliminate the host APCs by the alloreactive NK cells.[65,87]

Host-type APCs that are present and have been primed by conditioning are critical for the induction of this phase; recent evidence

suggests that donor-type APCs exacerbate GVHD, but in certain experimental models, donor-type APC chimeras also induce GVHD.[84,88-90] In clinical situations, if donor-type APCs are present in sufficient quantity and have been appropriately primed, they too might play a role in the initiation and exacerbation of GVHD.[91-93] Among the cells with antigen-presenting capability, dendritic cells (DCs) are the most potent and play an important role in the induction of GVHD.[94] Experimental data suggest that GVHD can be regulated by qualitatively or quantitatively modulating distinct DC subsets.[95-100] Langerhans cells were also shown to be sufficient for the induction of GVHD when all other APCs were unable to prime donor T cells, although the role for Langerhans cells when all APCs are intact is dispensable.[101,102] Studies have yet to define roles for other DC subsets. In one clinical study persistence of host DC after day 100 correlated with the severity of acute GVHD, whereas elimination of host DCs was associated with reduced severity of acute GVHD.[92] The allostimulatory capacity of mature monocyte-derived DCs (mDCs) after reduced intensity transplants was lower for up to 6 months compared with the mDCs from myeloablative transplant recipients, thus suggesting a role for host DCs and the reduction in danger signals secondary to less intense conditioning in acute GVHD.[103] Nonetheless this concept of enhanced host APC activation explains a number of clinical observations such as increased risks for acute GVHD associated with advanced-stage malignancy, conditioning intensity, and histories of viral infections.

Other professional APCs such as monocytes/macrophages or semiprofessional APCs might also play a role in this phase.[8] For example, recent data suggest that host-type B cells might play a regulatory role under certain contexts,[104] whereas in other contexts, they were dispensable for GVHD induction. Similarly, host basophils have been shown not to affect the induction or severity of acute GVHD.[105,106] Recent data suggest that radiosensitive hematopoietic-derived APCs may not be obligatory for induction of APCs. Also, host- or donor-type nonhematopoietic stem cells (such as mesenchymal stem cells, endothelial cells, epithelial cells, or stromal cells) can function as APCs in the context of inflammation. The role of these cells in the presence and absence of professional hematopoietic-derived APCs remains to be elucidated.

Phase 2: Donor-T-Cell Activation, Differentiation, and Migration

The infused donor T cells interact with the primed APCs leading to the initiation of the second phase of acute GVHD. This phase includes antigen presentation by primed APCs and the subsequent activation, proliferation, differentiation, and migration of alloreactive donor T cells. After allogeneic HSC transplants, both host- and donor-derived APCs are present in secondary lymphoid organs.[107,108] The T-cell receptor (TCR) of the donor T cells can recognize alloantigens either on host APCs (direct presentation) or donor APCs (indirect presentation).[109,110] In direct presentation, donor T cells recognize either the peptide bound to allogeneic MHC molecules or allogeneic MHC molecules without peptide.[110,111] During indirect presentation, T cells respond to the peptide generated by degradation of the allogeneic MHC molecules presented on self-MHC.[111] Experimental studies demonstrated that APCs derived from the host, rather than from the donor, are critical in inducing GVHD across MiHA mismatch.[8,109] Recent data suggest that presentation of distinct target antigens by the host- and donor-type APCs might play a differential role in mediating target organ damage.[8,112,113] In humans, most cases of acute GVHD developed when both host DCs and donor DCs were present in peripheral blood after BMT.[92]

Costimulation

The interaction of donor lymphocyte TCR with the host allopeptide presented on the MHC of APCs alone is insufficient to induce T-cell activation.[8,114] Both TCR ligation and costimulation via a "second" signal through interaction between the T cell costimulatory molecules and their ligands on APCs are required to achieve T proliferation, differentiation, and survival.[115] The danger signals generated in phase 1 augment these interactions, and significant progress has been made on the nature and impact of these second signals.[116,117] Costimulatory pathways are now known to deliver both positive and negative signals and molecules from two major families: the B7 family and the TNF receptor (TNFR) family play pivotal roles in GVHD.[118] Interruption of the second signal by blockade of various positive costimulatory molecules (CD28, ICOS, CD40, CD30, 4-1BB, and OX40) reduces acute GVHD in several murine models, whereas antagonism of the inhibitory signals (PD-1 and CTLA-4) exacerbates the severity of acute GVHD.[119-125] The various T cell and APC costimulatory molecules and the impact on acute GVHD are summarized in Table 109-3. The specific context and the hierarchy in which each of these signals plays a dominant role in the modulation of GVHD remain to be determined.

T-Cell Subsets

T cells consist of several subsets whose responses differ based on antigenic stimuli, activation thresholds, and effector functions. The alloantigen composition of the host determines which donor T-cell subsets proliferate and differentiate.

$CD4^+$ and $CD8^+$ Cells

CD4 and CD8 proteins are coreceptors for constant portions of MHC class II and class I molecules, respectively.[126] Therefore MHC class I (HLA-A, -B, -C) differences stimulate $CD8^+$ T cells and MHC class II (HLA-DR -DP, -DQ) differences stimulate $CD4^+$ T cells.[126-129] But clinical trials of $CD4^+$ or $CD8^+$ depletion have been inconclusive.[130] Perhaps this is not surprising, because in the majority of HLA-identical BMT, GVHD is induced by MiHAs, which

Table 109-3 T Cell-APC Interactions

T Cell	APC
ADHESION	
ICAMs	LFA-1
LFA-1	ICAMs

HVEM	LIGHT

HVEM, HSV glycoprotein D for herpesvirus entry mediator; *LIGHT,* homologous to lymphotoxins, shows inducible expression, and competes with HVEM, a receptor expressed by T lymphocytes.

are peptides derived from polymorphic cellular proteins that are presented by MHC molecules.[53] Because the manner of protein processing depends on genes of the MHC, two siblings will have many different peptides in the MHC groove.[53] Thus in the majority of HLA-identical BMT, acute GVHD can be induced by either or both $CD4^+$ and $CD8^+$ subsets in response to minor histocompatibility antigens.[130] The peptide repertoire for class I or class II MHC remains unknown and might even be unique in different individuals.[131] However, it is plausible that only a few of the many of these peptides might behave as immunodominant "major minor" antigens that can potentially induce GVHD. In any event, such antigens remain to be identified and validated in large patient population.

Naive and Memory Subsets

Intriguingly, several independent groups have found that although the naive ($CD62L^+$) T cells were alloreactive and caused acute GVHD, this was not the case for the memory ($CD62L^-$) T cells across different donor/recipient strain combinations.[132-135] Furthermore, expression of naive T-cell marker CD62L was also found to be critical for regulation of GVHD by donor natural regulatory T cells.[136] By contrast, another recent study demonstrated that alloreactive memory T cells and their precursor cells (memory stem cells) caused robust GVHD.[137,138] It remains as yet unknown whether the reduced GVHD potential of memory-type T cells from a naive murine donor, in contrast to their ability to cause greater solid organ allorejection,[139] is a consequence of the intense conditioning regimen and/or altered trafficking or from a restricted repertoire and/or T-cell intrinsic defect.

Regulatory T Cells

Recent advances indicate that distinct subsets of regulatory $CD4^+CD25^+$, $CD4^+CD25^-IL10^+$ Tr cells, γδT cells, DN^- T cells, NK T cells, and regulatory DCs control immune responses by induction of anergy or active suppression of alloreactive T cells.[96,97,140-148] Several studies have demonstrated a critical role for the natural donor $CD4^+CD25^+$ $Foxp3^+$ regulatory T (Treg) cells, obtained from naive animals or generated ex vivo, in the outcome of acute GVHD. Donor $CD4^+CD25^+$T cells suppressed the early expansion of alloreactive donor T cells and their capacity to induce acute GVHD without abrogating GVL effector function against these tumors.[149,150] $CD4^+CD25^+$ T cells induced and/or generated by of immature or regulatory host-type DCs and by regulatory donor-type myeloid APCs were also able to suppress acute GVHD.[96] One of the clinical studies that evaluated the relationship between donor $CD4^+CD25^+$ cells and acute GVHD in humans after matched sibling donor grafts found that in contrast to the murine studies, donor grafts containing larger numbers of $CD4^+$ $CD25^+$T cells developed more severe acute GVHD.[151] These data suggest that coexpression of $CD4^+$ and $CD25^+$ is insufficient because an increase in $CD25^+$ T cells in donor grafts is associated with greater risks for acute GVHD after clinical HCT. Another recent study found that Foxp3 mRNA expression (considered a specific marker for naturally occurring $CD4^+CD25^+$Tregs) was significantly decreased in peripheral blood mononuclear cells from patients with acute GVHD.[152,153] But Foxp3 expression in humans, unlike mice, may not be specific for T cells with a regulatory phenotype.[154] It is likely that the precise role of regulatory T cells in clinical acute GVHD will therefore depend not only on identification of specific molecular markers in addition to Foxp3 but also on the ability for ex vivo expansion of these cells in sufficient numbers. The presence of STAT1 signaling has been shown to enhance Treg-mediated suppression of GVHD.[155] Recent observations have demonstrated key roles for host APCs in the induction and for donor APCs in the sustenance of infused mature Tregs.[156] Several clinical trials are underway in the United States and Europe with attempts to substantially expand these cells ex vivo and use for prevention of GVHD. Emerging data from these trials suggest that donor Tregs can reduce incidence of clinical GVHD and do not prevent engraftment.[157]

Host $NK1.1^+$ T cells are another T-cell subset that has been shown to suppress acute GVHD in an IL-4 dependent manner.[147,148,158] By contrast, donor NKT cells were found to reduce GVHD and enhance perforin-mediated GVL in an IFN-γ dependent manner.[159,160] Recent clinical data suggest that enhancing recipient NKT cells by repeated TLI conditioning promoted Th2 polarization and dramatically reduced GVHD.[148] Experimental data also show that activated donor NK cells can reduce GVHD through the elimination of host APCs or by secretion of transforming growth factor-β (TGFβ) secretion.[160] A murine BMT study using mice lacking SH2-containing inositol phosphatase (SHIP), in which the NK compartment is dominated by cells that express two inhibitory receptors capable of binding either self or allogeneic MHC ligands, suggests that host NK cells may play a role in the initiation of GVHD.[161]

T-Cell Apoptosis

Deletional mechanisms of tolerance fall into two categories: (1) central (thymic) deletion and (2) peripheral deletion.[162] Central deletion is an effective way to eliminate continued thymic production of alloreactive T cells. To this end, lymphoablative treatments have been used as a condition to create a mixed hematopoietic chimeric state in murine BMT models.[163] In this strategy, donor cells seed the thymus and maturing donor-reactive T-cell clones are deleted through intrathymic apoptosis.[164,165] The proportion of the peripheral T-cell repertoire that can respond to allogeneic MHC antigens may play a critical role in the development of tolerance.[166] In the case of MHC-mismatched transplantation, the frequency of alloreactive T cells is at least five orders of magnitude greater than the frequency of peptide-specific T cells responding to a nominal antigen.[166,167] The pathways of T cell apoptosis by which peripheral deletion occurs can be broadly categorized into activation-induced cell death (AICD) and passive cell death (PCD).[166] An important mediator of AICD in T cells is the Fas receptor.[168] Activated T cells expressing the Fas molecule undergo apoptotic cell death when brought into contact with cells expressing Fas ligand. A critical role for Fas-mediated AICD has been clearly demonstrated in attenuation of acute GVHD by several Th1 cytokines.[42]

PCD, or "death by neglect," illustrates the exquisite dependence of activated T cells on growth factors (e.g., IL-2, IL-4, IL-7, and/or IL-15) for survival; apoptotic cell death in this instance is largely due to rapid downregulation of BCL2.[169-171] Transplantation of BCL-XL T cells into nonirradiated recipients significantly exacerbates GVHD; however, no difference in GVHD mortality is observed in animals that have been lethally irradiated.[172] Selective elimination of donor T cells in vivo after BMT using transgenic T cells in which a thymidine kinase (TK) suicide gene is targeted to T cells has also been shown to attenuate the severity of acute GVHD.[172-175] Another recent approach to prevent GVHD is the selective depletion of alloantigen-specific donor T cells by photodynamic cell purging process, wherein donor T cells are treated with photoactive 4,5-dibromorhodamine 123 and subsequently exposed to visible light.[176] Thus several deletional mechanisms have been shown to reduce acute GVHD but the conditions under which one or another of these deletional mechanisms predominate role remain to be determined.

Cytokines and T-Cell Differentiation

APC and T-cell activation result in rapid intracellular biochemical cascades that induce transcription of many genes, including cytokines and their receptors. The Th1 cytokines (IFN-γ, IL-2, and TNF-α) have been implicated in the pathophysiology of acute GVHD.[177-179] IL-2 production by donor T cells remains the main target of many current clinical therapeutic and prophylactic approaches, such as cyclosporine, tacrolimus, and monoclonal antibodies (mAbs) against the IL-2 and its receptor to control acute GVHD.[177,180] However, emerging data indicate an important role for IL-2 in the generation and maintenance of $CD4^+CD25^+$ $Foxp3^+$

Tregs, suggesting that prolonged interference with IL-2 may have an unintended consequence in the prevention of the development of long-term tolerance after allogeneic HCT.[181-184] Similarly, the role of other Th1 cytokines IFN-γ or their inducers as regulators or inducers of GVHD severity depends on the degree of allomismatch, the intensity of conditioning and the T-cell subsets that are involved after BMT.[185-187] Thus although the cytokine storm initiated in phase 1 and amplified by the Th1 cytokines correlates with the development of acute GVHD, early Th1 polarization of donor T cells to HCT recipients can attenuate acute GVHD suggesting that physiologic and adequate amounts of Th1 cytokines are critical for GVHD induction, whereas inadequate production (extremely low or high) could modulate acute GVHD through a breakdown of negative feedback mechanisms for activated donor T cells.[179,187-190] Several different cytokines that polarize donor T cells to Th2 such as IL-4, G-CSF, IL-18, IL-11, rapamycin, and the secretion of IL-4 by NK1.1$^+$ T cells can reduce acute GVHD.[191-198] However, Th1 and Th2 subsets cause injury of distinct acute GVHD target tissues, and some studies failed to show a beneficial effect of Th2 polarization on acute GVHD.[199] Thus the Th1/Th2 paradigm of donor T cells in the immunopathogenesis of acute GVHD has evolved over the last few years, and its causal role in acute GVHD is complex and incompletely understood.

IL-10 plays a key role in suppression of immune responses, and its role in regulating experimental acute GVHD is unclear.[122] Recent clinical data demonstrate an unequivocal association of IL-10 polymorphisms with the severity of acute GVHD.[72] TGF-β, another suppressive cytokine, was shown to suppress acute GVHD but to exacerbate chronic GVHD.[200] The roles of some other cytokines, such as IL-7 (which promotes immune reconstitution) and IL-13 remain unclear.[201-204] The role of IL-17–producing CD4$^+$ T cells (Th17)[205] in GVHD is also unclear at present. Initial studies showed that donor T cells deficient in IL-17A augmented Th1 differentiation and exacerbated acute GVHD.[206] In contrast, another study using a similar model showed that IL-17 contributed to CD4$^+$-mediated GVHD without affecting overall survival rates.[207] In addition, the differentiation of Th17 cells in vitro appeared to cause lethal acute GVHD with severe cutaneous and pulmonary damage.[208] More recently, IL-21, which is known to enhance Th17 cell differentiation while inhibiting the conversion of inducible Tregs from naive T cells,[209] has been shown to increase GVHD-induced injury.[210,211] Consistent with this finding, the abrogation of IL-21 signaling in donor T cells has led to reduced GVHD mortality, which is associated with donor Treg expansion and decreased TNF-α.[212] These conflicting results may be due to variations among the model systems, and further analyses are required to define the role of Th17 cells in GVHD.

CD4$^+$ and CD8$^+$ T Cells

As mentioned previously, in the majority of HLA-matched allogeneic HCTs, acute GVHD may be induced by either or both CD4$^+$ and CD8$^+$ subsets responses to MiHAs.[130] The repertoire and immunodominance of the GVHD-associated peptides presented by MHC class I and class II molecules have not been clearly defined.[131] One approach to retaining the beneficial GVL effects while eliminating the negative effects of GVHD is to selectively deplete subsets of donor alloreactive T cells in the hematopoietic cell inoculums using a TCR Vβ repertoire analysis with CDR3-size spectratyping.[213] More recently, it has been shown that GVL in allogeneic recipients could be restored without GVHD induction when the adoptive transfer of TCR-transduced allogeneic CD8$^+$ T cells was given in combination with PD-L1 blockade.[214]

Naive and Memory T Cells

T cells in murine models can be categorized into naive (CD62L$^+$ CD44$^-$), central memory (CD62L$^+$ CD44$^+$), and terminally differentiated effector/effector memory (CD62L$^-$ CD44$^-$) subsets. Donor naive CD62L$^+$ T cells are the primary alloreactive T cells that drive the GVHD reaction, whereas the donor effector memory CD62L$^-$ T cells do not.[132,133] Of interest, donor Treg cells expressing CD62L are critical to the regulation of GVHD.[136,215] Specifically, it has been shown that CD62L^{hi} Tregs attenuate GVHD and promote allogeneic BM engraftment.[109] The expression of CD62L is important for the migration of Tregs to secondary lymphoid organs, thereby inhibiting the initial expansion of donor T cells.[216] We now know that it is possible to modulate the alloreactivity of naive T cells by inducing anergy with costimulation blockade, deletion via cytokine modulation, or mixed chimerism. Donor effector memory T cells that are nonalloreactive do not induce GVHD, yet are able to transfer functional memory[132] and mediate GVL.[217] In addition, lymphopenia-induced proliferation gives rise to cells that are like memory T cells and enhance the GVL effect after DLI.[218] In contrast, memory T cells that are alloreactive can cause severe GVHD.[137,219,220] However, more recently, Anderson and colleagues demonstrated that enhancing the alloreactivity of effector memory T cells can cause GVHD, although a less severe and possibly more transient GVHD in nature. These findings may be better understood with further analyses that would enable tracking of alloantigen-specific T cells (naive, central memory, and effector memory subsets) in experimental GVHD and GVL models with defined TCR repertoires.

Leukocyte Migration

Donor T cells migrate to lymphoid tissues, recognize alloantigens on either host or donor APCs, and become activated. They then exit the lymphoid tissues and traffic to the target organs and cause tissue damage.[221] The molecular interactions necessary for T-cell migration and the role of lymphoid organs during acute GVHD have recently become the focus of a growing body of research. Chemokines play a critical role in the migration of immune cells to secondary lymphoid organs and target tissues.[222] T-lymphocyte production of macrophage inflammatory protein-1-alpha (MIP-1α) is critical to the recruitment of CD8$^+$ but not CD4$^+$ T cells to the liver, lung, and spleen during acute GVHD.[223] Several chemokines such as CCL2-5, CXCL2, CXCL9-11, CCL17, and CCL27 are overexpressed and might play a critical role in the migration of leukocyte subsets to target organs liver, spleen, skin, and lungs during acute GVHD.[221,224] CXCR3$^+$ T and CCR5$^+$ T cells cause acute GVHD in the liver and intestine.[221,225-227] CCR5 expression has also been found to be critical for Treg migration in GVHD.[228] In addition to chemokines and their receptors, expression of selectins and integrins and their ligands also regulate the migration of inflammatory cells to target organs.[222] For example, interaction between α4β7 integrin and its ligand MadCAM-1 are important for homing of donor T cells to Peyer patches and in the initiation of intestinal GVHD.[85,229] αLβ2/ICAM1, 2, 3 and α4β1/VCAM-2 interactions are important for homing to the lung and liver after experimental HCT.[221] The expression of CD62L on donor Tregs is critical for their regulation of acute GVHD, suggesting that their migration in secondary tissues is critical for their regulatory effects.[108] The migratory requirement of donor T cells to specific lymph nodes (e.g., Peyer patches) for the induction of GVHD might depend on other factors such as the conditioning regimen, inflammatory milieu, etc.[85,230] Furthermore, FTY720, a pharmacologic sphingosine-1-phosphate receptor agonist, inhibited GVHD in murine but not in canine models of HCT.[231,232] Thus significant species differences may also factor in the ability of these molecules to regulate GVHD.

Phase 3: Effector Phase

The effector phase that leads to the GVHD target organ damage is a complex cascade of multiple cellular and inflammatory effectors that further modulate each other's responses either simultaneously or successively. Effector mechanisms of acute GVHD can be grouped into cellular and inflammatory effectors. Inflammatory chemokines expressed in inflamed tissues upon stimulation by proinflammatory effectors, such as cytokines, are specialized for the recruitment of effector cells, such as cytotoxic T lymphocytes (CTLs).[233]

Furthermore the spatiotemporal expression of the cytochemokine gradients might determine not only the severity but also the unusual cluster of GVHD target organs (skin, gut, and liver).[221,234]

Cellular Effectors

CTLs are the major cellular effectors of GVHD.[235,236] The principle CTL effector pathways that have been evaluated after allogeneic BMT are the Fas-Fas ligand (FasL), the perforin-granzyme (or granule exocytosis), and the TNFR-like death receptors (DR), such as TNF-related apoptosis-inducing ligand (TRAIL: DR4, 5 ligand) and TNF-like weak inducers of apoptosis (TWEAK: DR3 ligand).[236-241] The involvement of each of these molecules in GVHD has been tested by utilizing donor cells that are unable to mediate each pathway. Perforin is stored in cytotoxic granules of CTLs and NK cells, together with granzymes and other proteins. Although the exact mechanisms remain unclear, following the recognition of a target cell through the TCR-MHC interaction, perforin is secreted and inserted into the cell-membrane, forming "perforin pores" that allow granzymes to enter the target cells and induce apoptosis through various downstream effector pathways such as caspases.[242] Ligation of Fas results in the formation of the death-inducing signaling complex (DISC) and also activates caspases.[243,244]

Transplantation of perforin-deficient T cells results in a marked delay in the onset of GVHD in transplants across MiHA disparities only, both MHC and MiHA disparities, and across isolated MHC I or II disparities.[236,245-249] However, mortality and clinical and histologic signs of GVHD were still induced even in the absence of perforin-dependent killing in these studies, demonstrating that the perforin-granzyme pathway plays little role in target organ damage. A role for the perforin-granzyme pathway for GVHD induction is also evident in studies employing donor T-cell subsets. Perforin- or granzyme B-deficient $CD8^+$ T cells caused less mortality than wild-type T cells in experimental transplants across a single MHC class I mismatch. This pathway, however, seems to be less important compared with Fas/FasL pathway in CD4-mediated GVHD.[248-250] Thus it seems that $CD4^+$ CTLs preferentially use the Fas-FasL pathway, whereas $CD8^+$ CTLs primarily use the perforin-granzyme pathway.

Fas, a TNF-receptor family member, is expressed by many tissues, including GVHD target organs.[251] Its expression can be upregulated by inflammatory cytokines such as IFN-γ and TNF-α during GVHD, and the expression of FasL is also increased on donor T cells, indicating that FasL-mediated cytotoxicity may be a particularly important effector pathway in GVHD.[236,252] FasL-defective T cells cause less GVHD in the liver, skin, and lymphoid organs.[247,250,252] The Fas-FasL pathway is particularly important in hepatic GVHD, consistent with the keen sensitivity of hepatocytes to Fas-mediated cytotoxicity in experimental models of murine hepatitis.[236] Fas-deficient recipients are protected from hepatic GVHD, but not from other organ GVHD, and administration of anti-FasL (but not anti-TNF) MAbs significantly blocked hepatic GVHD damage occurring in murine models.[236,253,254] Although the use of FasL-deficient donor T cells or the administration of neutralizing FasL MAbs had no effect on the development of intestinal GVHD in several studies, the Fas-FasL pathway may play a role in this target organ, because intestinal epithelial lymphocytes exhibit increased FasL-mediated killing potential.[255] Elevated serum levels of soluble FasL and Fas have also been observed in at least some patients with acute GVHD.[256,257]

The use of a perforin-granzyme and FasL cytotoxic double-deficient (cdd) mouse provides an opportunity to address whether other effector pathways are capable of inducing GVHD target organ pathology. An initial study demonstrated that cdd T cells were unable to induce lethal GVHD across MHC class I and class II disparities after sublethal irradiation.[246] However, subsequent studies demonstrated that cytotoxic effector mechanisms of donor T cells are critical in preventing host resistance to GVHD.[240,258] Thus when recipients were conditioned with lethal dose of irradiation, cdd $CD4^+$ T cells produced similar mortality to wild-type $CD4^+$ T cells.[240] These results were confirmed by a recent study demonstrating that GVHD target damage can occur in mice that lack alloantigen expression on the epithelium, preventing direct interaction between CTLs and target cells.[241]

The participation of another death ligand receptor signaling pathway, TNF/TNFRs, has also been evaluated. Experimental data suggest that this pathway is crucial for GI GVHD (discussed in more detail later). Recently, several additional TNF family apoptosis-inducing receptors/ligands have been identified, including TWEAK, TRAIL, and LTβ/LIGHT, all of which have been proposed to play a role in GVHD and GVL responses.[119,259-265] However, whether these distinct pathways play a more specific role for GVHD mediated by distinct T cell subsets in certain situations remains unknown. Intriguingly, recent data suggest that none of these pathways might be critical for mediating the rejection of donor grafts.[259,266] Thus it is likely that their role in GVHD might be modulated by the intensity of conditioning and by the recipient T-cell subsets. Existing experimental data suggest that perforin and TRAIL cytotoxic pathways are associated with $CD8^+$ T cell–mediated GVL.[236] The available experimental data are strongly skewed toward $CD8^+$ T cell–mediated GVL based on the dominant role of this effector population in most murine GVT models; however, $CD4^+$ T cells can mediate GVL and might be crucial in clinical BMT depending on the type of malignancy and the expression of immunodominant antigens.

Taken together, experimental data suggest some distinction between the use of different lytic pathways for the specific GVHD target organs and GVL, but the clinical applicability of these observations is as yet largely unknown.

Inflammatory Effectors

Inflammatory cytokines synergize with CTLs resulting in the amplification of local tissue injury and further promotion of an inflammation, which ultimately leads to the observed target tissue destruction in the transplant recipient.[267] Macrophages, which had been primed with IFN-γ during step 2, produce inflammatory cytokines TNF-α and IL-1 when stimulated by a secondary triggering signal.[268] This stimulus may be provided through toll-like receptors (TLRs) by microbial products such as LPS and other microbial particles, which can leak through the intestinal mucosa damaged by the conditioning regimen and gut GVHD.[269,270] It is now apparent that immune recognition through both TLR and non-TLRs (such as NOD) by the innate immune system also controls activation of adaptive immune responses.[269,271] Recent clinical studies of GVHD suggested the possible association with TLR/NOD polymorphisms and severity of GVHD.[75,272,273] LPS and other innate stimuli may stimulate gut-associated lymphocytes, keratinocytes, dermal fibroblasts, and macrophages to produce proinflammatory effectors that play a direct role in causing target organ damage. Indeed experimental data with MHC mismatched BMT suggest that under certain circumstances these inflammatory mediators are sufficient in causing GVHD damage even in the absence of direct CTL-induced damage.[88] The severity of GVHD appears to be directly related to the level of innate and adaptive immune cell priming and release of proinflammatory cytokines such as TNF-α, IL-1, and nitric oxide (NO).[42]

The cytokines TNF-α and IL-1 are produced by an abundance of cell types during processes of both innate and adaptive immunity; they often have synergistic, pleiotropic, and redundant effects on both activation and effector phases of GVHD.[179] A critical role for TNF-α in the pathophysiology of acute GVHD was first suggested over 20 years ago because mice transplanted with mixtures of allogeneic BM and T cells developed severe skin, gut, and lung lesions that were associated with high levels of TNF-α mRNA in these tissues.[274] Target organ damage could be inhibited by infusion of anti–TNF-α MAbs, and mortality could be reduced from 100% to 50% by the administration of the soluble form of the TNF-α receptor (sTNFR), an antagonist of TNF-α.[79,82,275] Accumulating experimental data further suggest that TNF-α is involved in a multistep process of GVHD pathophysiology. TNF-α can (1) cause cachexia, a characteristic feature of GVHD; (2) induce maturation of DCs,

thus enhancing alloantigen presentation; (3) recruit effector T cells, neutrophils, and monocytes into target organs through the induction of inflammatory chemokines; and (4) cause direct tissue damage by inducing apoptosis and necrosis. TNF-α also involves in donor-T-cell activation directly through its signaling via TNFR1 and TNFR2 on T cells. TNF-TNF1 interactions on donor T cells promote alloreactive T-cell responses and TNF-TNFR2 interactions are critical for intestinal GVHD.[262,276] TNF-α also seems to be an important effector molecule in GVHD in skin and lymphoid tissue.[274,277] Additionally, TNF-α might also be involved in hepatic GVHD, probably by enhancing effector cell migration to the liver via the induction of inflammatory chemokines.[278] An important role for TNF-α in clinical acute GVHD has been suggested by studies demonstrating elevated serum levels or TNF-α or elevated TNF-α mRNA expression in peripheral blood mononuclear cells in patients with acute GVHD and other endothelial complications, such as hepatic venoocclusive disease (VOD).[278-280] Phase I and II trials using TNF-α antagonists reduced the severity of GVHD, suggesting that it is a relevant effector in causing target organ damage.[281,282]

The second major proinflammatory cytokine that appears to play an important role in the effector phase of acute GVHD is IL-1.[42,267] Secretion of IL-1 appears to occur predominantly during the effector phase of GVHD of the spleen and skin, two major GVHD target organs.[283] A similar increase in mononuclear cell IL-1 mRNA has been shown during clinical acute GVHD. Indirect evidence of a role for IL-1 in GVHD was obtained with administration of this cytokine to recipients in an allogeneic murine BMT model. Mice receiving IL-1 displayed a wasting syndrome and increased mortality that appeared to be an accelerated form of disease. By contrast, intraperitoneal administration of IL-1 receptor antagonist (IL-1RA) starting on d 10 posttransplant was able to reverse the development of GVHD in the majority of animals, providing a significant survival advantage to treated animals.[284] However, the attempt to use IL-1RA to prevent acute GBHD in a randomized trial was not successful.[285]

As a result of activation during GVHD, macrophages also produce NO, which contributes to the deleterious effects on GVHD target tissues, particularly immunosuppression.[286] NO also inhibits the repair mechanisms of target tissue destruction by inhibiting proliferation of epithelial stem cells in the gut and skin.[287] In humans and rats, the development of GVHD is preceded by an increase in serum levels of NO oxidation products.[288-290]

Interleukin-6 has also been identified as a critical cytokine that promotes a proinflammatory response during GVHD and inhibits the reconstitution of Tregs.[291] While Tawara and colleagues confirmed an important role for IL-6 in GVHD, their findings were independent of T effector cell expansion or donor Treg responses. It is possible that reduction in GVHD is a consequence of direct reduction in IL-6–induced inflammation and cytopathic damage of the target tissues.[292]

Existing data demonstrate important roles for various inflammatory effectors in GVHD. However, the relevance of currently studied or as yet unknown specific effectors might be determined by other factors, including the intensity of preparatory regimens, the type of allograft, the T-cell subsets and the duration of BMT. In any event, both experimental and clinical data suggest an important role for both the cellular and inflammatory mediators in GVHD-induced target organ damage.

BIOMARKERS OF GRAFT-VERSUS-HOST DISEASE

Emerging data from large datasets have identified and validated biomarkers for acute GVHD. Screening of plasma with antibody microarrays for 120 proteins in a discovery set of 42 BMT patients that revealed eight potential biomarkers for diagnosis of GVHD. The authors then measured by enzyme-linked immunosorbent assay (ELISA) the levels of these biomarkers in samples from 424 BMT patients who were randomly divided into training (n = 282) and validation (n = 142) sets. Logistic regression analysis of these eight proteins determined a composite biomarker panel of four proteins (IL-2Rα, TNFR1, IL-8, and hepatocyte growth factor [HGF]) that optimally discriminated patients with and without GVHD. The receiver operating characteristic area under the curve (ROC AUC) that distinguished these two groups in the training set was 0.91 and 0.86 in the validation set. Cox regression analysis revealed that the biomarker panel predicted survival independently of GVHD severity. These biomarkers did not distinguish organ-specific disease.

An in-depth, unbiased, tandem MS (MS/MS)–based analysis of plasma was able to quantify proteins at low concentrations. The authors chose candidate biomarker proteins with concentrations at least twice as high in pooled samples from 10 BMT patients with histologically confirmed skin GVHD compared with pooled samples from 10 BMT patients without the disease. Among 66 candidate biomarkers, 14 were expressed primarily in the skin. Elafin (also known as peptidase inhibitor-3, skin-derived antileukoproteinase, or trappin-2) emerged as the lead biomarker candidate because suitable antibodies were available for high-throughput screening of plasma samples by ELISA. They validated the biomarker in a large group (492) of allogeneic BMT recipients. Blinded analysis of skin biopsies from 20 patients showed that positive elafin expression, defined as significant staining extending to a depth of more than 50% of the epidermis, was present in 7 of 10 cases of GVHD and in 0 of 10 cases of non-GVHD ($P = 0.003$). In the large data set, plasma elafin concentrations of patients with GVHD were 3.9 times higher than patients with a non-GVHD rash ($P < 0.001$). When elafin was compared with four previously reported diagnostic biomarkers of systemic acute GVHD (IL-2Rα, TNFR1, IL-8, and HGF), it was the best single biomarker, and the combination of all five biomarkers provided little further information. The prognostic value of the biomarker was also significant because patients with high elafin concentrations at GVHD onset died three times as often as those with low concentrations, and the 5-year overall survival was significantly higher in the low-elafin group: 48% versus 26% ($P = 0.01$). When survival was modeled simultaneously on elafin concentration, GVHD skin stage at onset, and the other prognostic factors, the association between elafin concentration and risk for mortality remained statistically significant ($P = 0.02$).

In a follow-up study the authors also identified and validated regenerating islet-derived 3-alpha (REG3α) as a biomarker of gastrointestinal GVHD. Using an identical proteomics approach, they first identified and quantified 562 proteins of which 74 were increased at least two-fold in patients with GVHD. Five proteins (carboxypeptidase N catalytic chain precursor; pancreatic secretory trypsin inhibitor precursor; palladin; lithostathine 1α precursor; and REG3α) were preferentially expressed in the GI tract. They validated the biomarker in samples from 871 allogeneic BMT recipients. Plasma REG3α concentrations were three times higher in patients at the onset of GI GVHD than in all other patients, including those with non-GVHD enteritis. Serum REG3α concentrations were also higher in GI GVHD in an independent validation set of 143 BMT patients from Regensburg, Germany and Kyushu, Japan. In patients with diarrhea caused by GVHD, REG3α concentrations at the onset of GVHD were five times higher than in patients with diarrhea from other causes. REG3α was the best single diagnostic biomarker at the onset of symptoms of lower GI GVHD, and additional biomarkers provided no further increased sensitivity or specificity. Using REG3α at the median concentration provided a positive predictive value (PPV) of 95% and a negative predictive value (NPV) of 32% for GVHD as the etiology of diarrhea. REG3α concentrations were threefold higher at the time of GVHD diagnosis in patients who had no response to therapy at 4 weeks than in patients who experienced a complete or partial response ($p < 0.001$). When patients were divided into two equal groups based on REG3α concentrations, transplant related mortality (TRM) was twice as high in patients with high REG3α group, and this difference remained significant after adjusting for known risk factors of donor type, degree of HLA match, conditioning intensity, age and baseline disease severity ($p < 0.001$). In further analyses, the plasma concentration of REG3α, the clinical severity of GVHD, the histologic severity at GVHD diagnosis independently predicted lack of response to GVHD therapy 4 weeks following treatment and TRM. Patients who had all three risk factors

experienced significantly greater NRM than those with any two of the risk factors (86% versus 66%, p <0.001). The integration of clinical stage, histologic grade, and REG3α plasma concentrations into a single grading system will permit better risk stratification and rapid identification of those patients with severe GI damage in whom standard treatment is likely to be insufficient. This study provides potential new insights into the biology of GI GVHD. REG proteins act downstream of IL-22 to protect the epithelial barrier function of the intestinal mucosa through the binding of bacterial peptidoglycans. Intestinal stem cells (ISCs) are principal cellular targets of GVHD in the GI tract, where intestinal flora are critical for amplification of GVHD damage. A leading hypothesis is that ISCs are protected by antibacterial proteins such as REG3α secreted by neighboring Paneth cells into the crypt microenvironment. If death of an intestinal stem cell eventually manifests itself as denudation of the mucosa, the patchy nature of GVHD histologic damage may be explained as the lack of mucosal regeneration following the dropout of individual ISCs. The tight proximity of Paneth cells with ISCs concentrates their secretory contents in that vicinity, so that mucosal barrier disruption caused by stem cell dropout may preferentially allow Paneth cell proteins, including REG3α, to traverse into the bloodstream. Thus the plasma levels of REG3α may serve as a surrogate marker for the cumulative area of these breaches to GI mucosal barrier integrity, a parameter impossible to measure by individual tissue biopsies. Such an estimate of total damage to the mucosal barrier may also help explain the prognostic value of REG3α with respect to therapy responsiveness and NRM.

Less progress has been made with biomarkers for chronic GVHD. One important study, published by the Children's Oncology Group, analyzed candidate biomarkers in 52 patients with extensive chronic GVHD who had participated in a phase III therapeutic trial. Patients were compared for time of onset after BMT (early, 3 to 8 months; late, 9 months or more) with 28 time-matched controls without chronic GVHD. Soluble B-cell activation factor (sBAFF), anti-dsDNA antibody, soluble IL-2 receptor alpha (sIL-2Rα), and soluble CD13 (sCD13) were elevated in patients with early-onset chronic GVHD. sBAFF and anti-dsDNA were also elevated in patients with late-onset chronic GVHD. For the early chronic GVHD group, ROC AUCs were 0.70 for anti-dsDNA (0.66), IL2Rα (0.83), sCD13 (0.77), and sBAFF (0.70). At 90% specificity, the sensitivity was relatively low, ranging between 42% and 53%. A panel of biomarkers slightly improved the diagnostic power. In terms of prognosis, only IL-2Rα demonstrated a significant difference between responders and nonresponders ($P = 0.03$). These biomarkers need to be validated in much larger cohorts before definitive conclusions can be drawn.

Prevention of Acute Graft-Versus-Host Disease

Elimination of T cells with monoclonal antibodies, immunotoxins, lectins, CD34 columns, or physical techniques are effective at reducing GVHD. A typical unmanipulated marrow transplant entails the infusion of ≈10^7 T cells per kg of recipient weight. A T-cell dose ≤10^5 per kg has been associated with complete control of GVHD.[41] More recently, the combination of very high stem cell numbers and <3 × 10^4CD3 cells/kg allowed haploidentical transplantation without GVHD.[293] Presumably, host immune cells that survive the initial conditioning are responsible for graft rejection. When the stem cell source contains a large numbers of T cells, the GVH reaction further reduces the residual population capable of alloreactivity, thus decreasing graft rejection. To some degree, the higher graft failure rates may be controlled by increasing the intensity of the immunosuppression of the conditioning regimen,[294,295] or adding back T cells.[296] Overall there has been no improvement in survival that can be definitively attributed to T-cell depletion.

Treatment of established GVHD with specific T-cell antibodies has produced mixed results. Although antithymocyte globulin has definite activity in established GVHD, the nonspecific clearance of T cells may result in increased opportunistic infections and no improvement in survival. More specific therapy with humanized anti-IL-2 receptor antibody, daclizumab[297,298] or the humanized anti-CD3 antibody, visilizumab[299,300] are promising, since they offer the potential of selectively removing the activated T cells. However, an increased risk for infection may still be observed.[301]

The first generally prescribed GVHD preventive regimen was the administration of intermittent low-dose methotrexate as developed in a dog model by Thomas and Storb.[302] The principle of this approach was to administer a cell cycle–specific chemotherapeutic agent immediately after the transplant, when the T cells have started to divide after exposure to allogeneic antigens. Subsequently, the addition of antithymocyte globulin, prednisone, or both resulted in incremental improvement in the GVHD rate but no improvement in survival.[303,304] Ultimately, the course of methotrexate was abbreviated and combined with a T-cell activation inhibitor, such as cyclosporine or tacrolimus. The introduction of cyclosporine in the late 1970s was a significant advance in GVHD prevention. A similar agent, tacrolimus, has been shown to provide similar control of GVHD.[305] As a single agent, cyclosporine was about as effective as methotrexate.[306] However, in combination with methotrexate, there was a significant reduction in the incidence of GVHD and an improvement in survival.[307] Subsequent trials of tacrolimus and methotrexate compared with cyclosporine and methotrexate showed no advantage for either combination.[305] The addition of prednisone to the conventional two-drug regimen resulted in similar rates of GVHD and no improvement in survival.[308]

Sirolimus (rapamycin) is a macrocyclic lactone immunosuppressant that is similar in structure to tacrolimus and cyclosporine. All three drugs bind to immunophilins; however, sirolimus complexed with FKBP12 inhibits T-cell proliferation by interfering with signal transduction and cell-cycle progression and can prevent GVHD.[309] Because Sirolimus acts through a separate mechanism from the tacrolimus-FKBP complex (and cyclosporine-cyclophilin complex), it is synergistic with both tacrolimus and cyclosporine. More recently, mycophenolate mofetil (MMF) has been studied. It is the prodrug of mycophenolic acid (MPA), a selective inhibitor of inosine monophosphate dehydrogenase, an enzyme critical to the de novo synthesis of guanosine nucleotide. Since T lymphocytes are more dependent on such synthesis than myeloid or mucosal cells, MPA preferentially inhibits proliferative responses of T cells.[310]

One hypothesis that flows from the three-step model of GVHD posits that reduction of intestinal colonization with bacteria could prevent GVHD. Animal studies in germ-free environments support this notion; GVHD was not observed until mice were colonized with gram-negative organisms.[311] Later, gut decontamination and use of a laminar air flow environment was associated with less GVHD and better survival in patients with severe aplastic anemia.[312] Similarly, studies of intestinal decontamination in patients with malignancies have shown less GVHD in some,[313,314] but not all, studies.[315] Finally, another recent approach to GVHD prevention has been the use of nonmyeloablative conditioning transplants. A less intensive preparative regimen decreases the tissue toxicity and subsequent release of cytokines in animal models.[79,82] Patients generally experience mild toxicity in the initial peritransplant period and develop little or no GVHD, although many develop GVHD later, especially after donor lymphocyte infusions. In fact, the rates of GVHD are often higher than with conventional transplants, and GVHD is associated with a significant portion of the GVL effect.[316-318]

An important role for TNFα in clinical acute GVHD has been suggested by studies demonstrating elevated levels of TNFα in the serum of patients with acute GVHD and other endothelial complications such as venoocclusive disease.[280,319-321] Therapy of GVHD with humanized anti-TNFα (infliximab)[322,323] or a dimeric fusion protein consisting of the extracellular ligand-binding portion of the human TNFα receptor (TNFR) linked to the Fc portion of human IgG1 (etanercept)[324] have shown some promise.[325,326] The second major proinflammatory cytokine that appears to play an important role in the effector phase of acute GVHD is IL-1. Secretion of IL-1 appears to occur predominantly during the effector phase of GVHD in the spleen and skin, two major GVHD target organs.[283] IL-1RA is a naturally occurring pure competitive inhibitor of IL-1 that is produced

by monocytes/macrophages and keratinocytes. Of note, the IL-1RA gene is polymorphic, and the presence in the donor of the allele that is linked to higher secretion of IL-1RA was associated with less acute GVHD.[327] Two-phase I/II trials showed promising data that specific inhibition of IL-1 with either the soluble receptor or IL-1RA could result in remissions in 50% to 60% of patients with steroid-resistant GVHD.[328,329] However, a subsequent randomized trial of the addition of IL-1RA or placebo to cyclosporine and methotrexate beginning at the time of conditioning and continuing through day 14 after stem cell infusion did not show any protective effect of the drug, despite the attainment of very high plasma levels.[285,330] Therefore, at least as administered in this study, IL-1 inhibition was insufficient to prevent GVHD in humans. IL-11 was also able to protect the GI tract in animal models and prevent GVHD, but it did not prevent clinical GVHD.[330] Thus not all preclinical strategies successfully translate to new therapies.

Therapy for Acute Graft-Versus-Host Disease

Glucocorticoid steroids are the initial therapy for acute GVHD. The mechanisms by which steroids work are multifactorial; they act as lympholytic agents and inhibit the release of inflammatory cytokines such as IL-1, IL-2, IL-6, gamma interferon, and TNFα. Because of its intravenous availability, methylprednisolone is the steroid most commonly given for acute GVHD. Various dosing regimens have been used, none of which is clearly superior. High-bolus doses (10 to 20 mg/kg or 500 mg/m^2) have higher initial response rates, but flares on tapering and opportunistic infections are common. Both the Seattle and Minnesota transplant groups have found that treatment with steroids was as effective as, or more effective than, other therapies or combination of therapies, with 20% to 40% of patients having durable long-term responses.[331,332] Long-term salvage rates for patients who did not respond to steroids were 20% or less; most patients eventually died from infection, acute GVHD, and/or chronic GVHD. More recently, a randomized trial demonstrated that topical therapy with oral budosenide can have prednisone sparing effects and is efficacious in treatment of GI GVHD.[333] Clinically, two types of failure of corticosteroid treatment of acute GVHD can be distinguished: true steroid resistance (i.e., progression of GVHD symptoms and manifestations while patients are receiving full-dose corticosteroid treatment) and steroid dependence (i.e., reoccurrence [or flare] of GVHD during or after tapering of steroid treatment).[334] In general, the prognosis with true steroid-resistant GVHD is worse than the prognosis of steroid-dependent patients.[334] A comparison of trials dealing with steroid-resistant GVHD is hampered by variable inclusion of both patient groups in many of these trials. A number of agents have been tested, including chemical immunosuppressants such as MMF, ATG, anti-CD3 anti-T cell antibodies, and more specific agents directed against activation or adhesion molecules anti-CD25, anti-CD147, or cytokines or extracorporeal photopheresis.[334,335] To date, there are no randomized trails testing one agent versus the other in this clinical situation. Recent data suggested a role for TNF inhibition when added to steroids in treating GVHD, although a randomized trail failed to demonstrate any difference when compared with the addition of pentostatin or anti-IL2 to steroids and was inferior to the addition of MMF.[325,336]

Targeted elimination of alloreactive T cells has recently been demonstrated to be a safe and efficacious method to mitigate GVHD. Fusion of human caspase 9 to a modified human FK-binding protein that allowed for dimerization when exposed to a synthetic dimerizing drug led to the rapid death of 90% of alloreactive T cells expressing this construct and mitigated acute GVHD in a pilot trial of five patients following haploidentical BMT.[337]

Other Supportive Approaches

Infections are the main cause of death in patients with steroid-refractory acute GVHD, and careful surveillance and control of infections is mandatory in patients with acute GVHD. Fungal infections, especially aspergillosis, are the leading complication. Prophylaxis and early aggressive treatment should be facilitated by the introduction of new azoles (voriconazole, posiconozole) or echinocandins (caspofungin, micafungin), which broaden therapeutic efficacy with acceptable toxicity. Other supplementary approaches have been suggested, such as the use of octreotide[338] and oral beclomethasone (or budesonide) to control large volumes of diarrhea.[333]

CHRONIC GRAFT-VERSUS-HOST DISEASE

Chronic GVHD was initially defined as a GVHD syndrome presenting more than 100 days after transplant; its onset occurred either as an extension of acute GVHD (progressive), after a disease-free interval (quiescent), or with no precedent (de novo).[339,340] Chronic GVHD may be limited or extensive (see Table 109-3). Any grade of acute GVHD increases the probability of chronic GVHD, although no singular pathologic feature of the former predicts the development of the latter. Its incidence ranges from 30% to 60% after transplantation with the bone marrow, although it may be higher after peripheral blood progenitor transplants.[341]

As with acute GVHD, the immune system appears to be affected in all patients, who are highly susceptible to bacterial, viral, fungal, and opportunistic infections. Specific abnormalities of cellular immunity include decreases in the production of antibodies against specific antigens, defects in the number and function of CD4$^+$ T cells, and increases in the number of nonspecific suppressor cells, which further diminish lymphocyte responses. Skin changes resembling widespread lichen planus with papulosquamous dermatitis, plaques, desquamation, dyspigmentation, and vitiligo occur in 80% of patients.[318,342] Destruction of dermal appendages leads to alopecia and onychodysplasia. Severe chronic GVHD of the skin can resemble scleroderma, with induration, joint contractures, atrophy, and chronic skin ulcers. Chronic cholestatic liver disease occurs in 80% of patients and often resembles acute GVHD; it rarely progresses to cirrhosis. Severe mucositis of the mouth and esophagus can result in weight loss and malnutrition. Intestinal involvement, however, is infrequent.[318,342] Chronic GVHD also produces a sicca syndrome, with atrophy and dryness of mucosal surfaces caused by lymphocytic destruction of exocrine glands, usually affecting the eyes, mouth, airways, skin, and esophagus.[25,342,343] The hematopoietic system may also be affected, and thrombocytopenia is an unfavorable prognostic factor in patients with chronic GVHD.[318] Important predictors of unfavorable outcome are progressive onset, lichenoid skin changes, elevated serum bilirubin level, continued thrombocytopenia, and failure to respond to 9 months of therapy.[318,344-346] Among patients with none of these risk factors, 70% are expected to survive, compared with less than 20% with two or more of these risk factors.[346]

Histologic examination of the immune system reveals involution of thymic epithelium, disappearance of Hassall corpuscles, depletion of lymphocytes, and absence of secondary germinal centers in lymph nodes.[343] Pathologic skin findings include epidermal atrophy with changes characteristic of lichen planus and striking inflammation around eccrine units. Sclerosis of the dermis and fibrosis of the hypodermis subsequently develop. GI lesions include localized inflammation of the mucosa and stricture formation in the esophagus and small intestine.[342] Histologic findings in the liver are often similar to those that occur in acute GVHD but are more intense, with chronic changes such as fibrosis and hyalinization of portal triads, obliteration of bile ducts, and hepatocellular cholestasis.[318] The endocrine glands of the eyes, mouth, esophagus, and bronchi show destruction focused on centrally draining ducts, with secondary involvement of alveolar components.[343] Findings of bronchiolitis obliterans, similar to those that occur in rejection of lung transplants, are now generally considered a pulmonary manifestation of chronic GVHD, although the pathogenesis of this process remains unclear.[343]

Clinical Manifestations of Chronic Graft-Versus-Host Disease

Chronic GVHD can present with a plethora of clinical manifestations. Because of its unpredictable pattern and the late onset, when patients are no longer receiving care at their transplant center, the diagnosis is often delayed or not recognized. The staging of chronic GVHD is summarized in Table 109-4. However, consensus criteria recently developed by the National Institutes of Health (NIH) might soon become the standard for diagnosing and evaluating responses for chronic GVHD.[347,348]

Dermatologic

Skin involvement in chronic GVHD presents with varied features. Lichenoid chronic GVHD presents as an erythematous, papular rash that resembles lichen planus with no typical distribution pattern.[25] Scleradermatous GVHD may involve the dermis and/or the muscular fascia and clinically resembles systemic sclerosis. The skin is thickened, tight, and fragile, with very poor wound healing. Either hypo- or hyperpigmentation may occur. In severe cases the skin may become blistered and ulcerate. Hair changes can include increased brittleness, premature graying, and alopecia. Fingernails and toenails may also be affected by chronic GVHD. Destruction of sweat glands can cause hyperthermia.[349]

Ocular

Ocular GVHD usually presents with xerophthalmia or dry eyes. Irreversible destruction of the lacrimal glands results in dryness, photophobia, and burning. Local therapy with preservative-free tears and ointment or the placement of punctal plugs by an ophthalmologist might be required. Conjunctival GVHD, a rare manifestation of severe chronic GVHD, has a poor prognosis.[25,349]

Oral

Oral GVHD causes xerostomia and/or food sensitivity.[349] More advanced disease may cause odynophagia due to esophageal damage and strictures, although esophageal involvement occurs rarely without oral disease. Physical examination may reveal only erythema with a few white plaques, prompting a misdiagnosis of thrush or herpetic infections. Lichenoid changes in advanced disease can cause extensive plaque formation.[25]

Gastrointestinal

Patients with chronic GVHD have GI complaints that mimic other disease states, including acute GVHD, infection, dysmotility, lactose intolerance, pancreatic insufficiency, and drug-related side effects. In one retrospective review of the intestinal biopsies of patients with chronic GVHD and persistent GI symptoms, a majority of patients had evidence of both acute and chronic GVHD, and only 7% of the patients had isolated chronic GVHD.[25,342] Thus although chronic GVHD may involve the GI tract alone, it may be difficult to diagnose in those circumstances without concurrent acute GVHD.

Hepatic

Hepatic disease typically presents as cholestasis with elevated serum levels of alkaline phosphatase and bilirubin. Isolated hepatic chronic GVHD has become more common with the increasing use of donor lymphocyte infusions.[12] Liver biopsy is required to confirm the diagnosis of chronic hepatic GVHD in patients with no other target organ involvement.

Pulmonary

Bronchiolitis obliterans is a late and serious manifestation of chronic GVHD. Patients typically present with a cough or dyspnea.[349] Severe sclerotic disease of the chest wall may also give rise to similar symptoms with no intrinsic pulmonary disease. Pulmonary function tests demonstrate obstructive physiology and a reduction in DLCO. Chest computed tomography results may be normal or may show hyperinflation with a ground-glass appearance. Overall, patients with bronchiolitis obliterans have minimal response to therapy and a very poor prognosis. Patients with chronic GVHD are also at risk for chronic sinopulmonary infections, but symptoms may be minimal.[25]

Hematopoietic

Cytopenias in chronic GVHD are common. This may be a result of stromal damage, but autoimmune neutropenia, anemia, and/or thrombocytopenia are also seen. Thrombocytopenia at the time of chronic GVHD diagnosis is associated with poor prognosis. However, thrombocytopenia posttransplant is a poor prognostic factor regardless of GVHD, and eosinophilia is occasionally seen with chronic GVHD.

Table 109-4 Commonly Administered Drugs for Graft-Versus-Host Disease Prophylaxis and Treatment

Drug	Mechanism	Adverse Effects
Corticosteroids	Direct lymphocyte toxicity; suppress proinflammatory cytokines such as TNF-α	Hyperglycemia; acute psychosis; severe myopathy; neuropathy; osteoporosis; cataract development
Methotrexate (MTX)	Antimetabolite: inhibit T cell proliferation	Significant renal, hepatic, and gastrointestinal toxicities
Cyclosporine A (CSA)	IL-2 suppressor; blocks $Ca2^{+}$-dependent signal transduction distal to TCR engagement	Renal and hepatic insufficiency; hypertension; hyperglycemia; headache; nausea and vomiting; hirsutism; gum hypertrophy; seizure with severe toxicity
Tacrolimus (FK506)	IL-2 receptor; blocks $Ca2^{+}$-dependent signal transduction distal to TCR engagement	Similar to CSA
Mycophenolate mofetil (MMF)	Inhibits de novo purine synthesis	Body aches; abdominal pain; nausea and vomiting; diarrhea; neutropenia
Sirolimus	mTOR inhibitor	Thrombocytopenia; hyperlipidemia, TTP
Antithymocyte globulin (ATG)	Polyclonal immunoglobulin	Anaphylaxis; serum sickness

Immunologic

Chronic GVHD is inherently immunosuppressive. Functional asplenia with an increased susceptibility to encapsulated bacteria is common, and circulating Howell-Jolly bodies can be seen on peripheral blood smear. Patients are also at risk for invasive fungal infections and *Pneumocystis carinii* pneumonia (PCP). Hypoglobulinemia is common, and patients with levels below 500 mg/dL should be supplemented with intravenous immunoglobulin.

Musculoskeletal

Fascial involvement in sclerodermatous GVHD is usually associated with skin changes. Fasciitis in joint areas can cause severe restriction of range of motion. Muscle cramps are a common complaint in patients with chronic GVHD, but myositis with elevated muscle enzymes is rare. Many patients with chronic GVHD are on steroid therapy and have low levels of sex hormone posttransplant. Thus avascular necrosis, osteopenia, and osteoporosis are frequent complications.

Although several cases have been described, it is yet to be determined in large studies whether kidneys, which are primary targets in some animal models of chronic GVHD, are also involved.[350] Among the myriad clinical features of chronic GVHD, three definitive signs appear to be risk factors for increased mortality: (1) extensive skin GVHD involving >50% of the body surface area, (2) platelet count of <100,000/μL, and (3)progressive onset and acute GVHD that continues uninterrupted beyond day 100.[351] However, chronic GVHD remains, except in cases with obvious features, a difficult diagnosis; response to therapy is even more difficult to assess. Recent criteria established by NIH consensus conference might prove to be beneficial in establishing uniform guidelines for diagnosis, treatment, and response.[348] The NIH consensus criteria are currently being evaluated.

Differential Diagnosis

The distinction between chronic and acute GVHD has been traditionally based on the time of onset. However, with the advent of low-intensity HCT, that distinction has become less relevant. The NIH Working Group has, in addition to the two main categories of GVHD, added two subcategories. The broad category of acute GVHD includes (1) classic acute GVHD (maculopapular rash, nausea, vomiting, anorexia, profuse diarrhea, ileus, or cholestatic hepatitis), occurring within 100 days after transplantation or DLI (without diagnostic or distinctive signs of chronic GVHD), and (2) persistent, recurrent, or late acute GVHD: features of classic acute GVHD without diagnostic or distinctive manifestations of chronic GVHD occurring beyond 100 days of transplantation or DLI (often seen after withdrawal of immune suppression). The broad category of chronic GVHD includes (1) classic chronic GVHD without features characteristic of acute GVHD and (2) an overlap syndrome in which features of chronic and acute GVHD appear together. In the absence of histologic or clinical signs or symptoms of chronic GVHD, the persistence, recurrence, or new onset of characteristic skin, GI tract, or liver abnormalities should be classified as acute GVHD regardless of the time after transplantation. With appropriate stratification, patients with persistent, recurrent, or late acute GVHD or overlap syndrome can be included in clinical trials with patients who have chronic GVHD.

CHRONIC GRAFT-VERSUS-HOST DISEASE: PATHOPHYSIOLOGY

The pathophysiology of chronic GVHD is generally much less well understood than that of acute GVHD and has undergone less intensive experimental modeling.[25] It is important to recognize that chronic GVHD was originally defined as a temporal rather than a clinical or pathophysiologic entity. The initial clinical reports of chronic GVHD described abnormalities that occurred at least 150 days after stem cell infusion.[352,353] By convention, day 100 after stem cell infusion is used as an arbitrary divider between acute and chronic GVHD. But some manifestations of acute GVHD occur after day 100, and some manifestations of chronic GVHD may occur before day 100. Thus it is preferable to consider the clinical symptoms and signs per se rather than their timing of onset.

Relatively little is known about the pathophysiology of chronic GVHD. This is due in part to the absence of appropriate animal models that can capture the kinetics and the protean manifestation of chronic GVHD.[354] Based on certain clinical features chronic GVHD has been considered to be an autoimmune disease, with some experimental data suggesting that chronic GVHD results from defective central negative selection, which leads to the generation of autoreactive clones that escape tolerogenic mechanisms operating in the periphery.[355,356] This would indicate that the nonpolymorphic antigens expressed in both the donor and recipient rather than MiHA antigens are the likely targets. In contrast to T cells from animals with acute GVHD that are specific for host alloantigens, T cells from animals with chronic GVHD are specific for a public (common) determinant of MHC class II molecules.[357,358] These T cells are considered autoreactive because they recognize public MHC class II determinants that are common to both donor and recipient rather than polymorphic histocompatibility antigens that are specific for the host. The autoreactive cells of chronic GVHD are associated with a damaged thymus, which can be injured by several mechanisms, including acute GVHD, the conditioning regimen, or age-related involution and atrophy. In chronic GVHD the ability of the thymus to delete autoreactive T cells (negative selection) and to induce tolerance is impaired.[25,359,360] However, no clear data exist on the isolation of "autoreactive" donor-derived T-cell clones that equally recognize nonpolymorphic antigens from the donor and recipient cells. This, however, does not directly preclude the existence of a causative role for autoreactive T cells. Chronic GVHD could also be a product of T cells that have undergone relatively chronic antigen stimulation as a result of the presence of inexhaustible and ubiquitous MiHA antigens. Allo-T cells under circumstances of chronic MiHA antigen stimulation can induce syndromes resembling those induced by the chronic antigen stimulation in autoimmune diseases. This concept is also consistent with the proposal of acute GVHD as a risk factor for chronic GVHD. The antigens targeted in chronic GVHD could be the same dominant ones targeted in acute GVHD, but the reactive T cells could be different; for example, they may secrete transforming growth factor-β. However, antigens other than those that were initially immunodominant (even those not initially targeted but introduced through epitope spread of either the nonpolymorphic "autoantigens" or the now-distinct MiHAs) could be important. It is also conceivable that regulatory mechanisms could frequently fail in allo-HCT, resulting in activation and expansion of T cells that recognize both nonpolymorphic and MiHA epitopes. One recent murine study suggested that development of chronic GVHD-like syndrome is target antigen-dependent.[112] Furthermore, chronic GVHD pathogenesis could, in part, be a consequence of T cell priming by donor-derived antigen-presenting cells.[113] In some patient subsets, responses to rituximab, presence of MiHA-specific antibodies, and the presence of chronic GVHD after TCD allo-BMT would indicate that in addition to donor T cells, donor B cells might be a direct effector or might have a role in priming T cells as APCs.[361,362] Given the myriad clinical presentations of chronic GVHD that tend to occur at variable times after HCT, it is possible that separate pathogenic mechanisms are involved in causing distinct manifestations and that no single putative mechanism is sufficient to cause chronic GVHD. Nonetheless, a recent murine model demonstrated a pathogenic role for donor B cells and alloantibody production in causing experimental chronic GVHD.

THERAPY FOR CHRONIC GRAFT-VERSUS-HOST DISEASE

Chronic GVHD has a major impact on both quality of life and survival, frequently involves multiple organs, and necessitates

prolonged immunosuppressive therapy.[363] One report noted that 15% of cancer-free patients were still receiving immunosuppressive therapy after 7 years.[364] The more severe forms of chronic GVHD are clearly associated with a lower disease-free survival. Thus the potential benefit of a graft-versus-leukemia effect is shadowed by significant treatment-related mortality.[364]

Current therapies for chronic GVHD are of limited efficacy, and there is no long-term satisfactory regimen for patients who do not respond to front-line steroid-based therapy. Indeed, no medication has been approved by the Food and Drug Administration (FDA) for use in chronic GVHD. The lack of standardized response criteria to measure therapeutic efficacy poses a major obstacle to pursuing therapeutic trials in chronic GVHD. Overall survival and/or discontinuation of systemic immunosuppression are accepted long-term endpoints in chronic GVHD trials. The recent NIH-sponsored consensus project provided, for the first time, a set of standardized measures and definitions to use as response criteria in chronic GVHD.[347,348] Nonetheless, these recommendations are yet to be tested and validated in prospective studies. The NIH consensus conference has defined response measures classified in two main groups: clinician-assessed and patient-reported (Table 109-5).[354]

The prevention of acute GVHD has not consistently resulted in a lower incidence of chronic GVHD. A clear example is the use of reduced-intensity transplants, consistently associated with a lower incidence of acute GVHD but with no major impact on chronic GVHD.[258,365] The extended use of GVHD prophylaxis with cyclosporine, or variations in the cyclosporine dosage used, showed no beneficial effects on the incidence of chronic GVHD.[363,366] The addition of thalidomide to cyclosporine and methotrexate prophylaxis, the administration of IV Ig, and early treatment based on biopsy findings of subclinical GVHD in an attempt to preemptively treat chronic GVHD were unsuccessful.[363] The most commonly used therapies to treat chronic GVHD are cyclosporine A (CSA) and prednisone. Sullivan and colleagues[367] reported that prednisone alone is superior to prednisone plus azathioprine for primary treatment of patients with chronic GVHD. However, in patients classified as high-risk on the basis of platelet counts below 100,000/μL, treatment with prednisone alone resulted in only 26% 5-year survival. When a similar group of patients was treated with alternating-day CSA and prednisone, 5-year survival exceeded 50%.[368] A recent randomized study of 287 patients with extensive GVHD found no statistically significant difference in nonrelapse death at 5 years or in cumulative incidence of secondary therapy at 5 years when prednisone alone was compared with prednisone plus CSA.[25] For chronic GVHD that recurs or fails to respond to initial therapy, there is no standard treatment. Experimental therapies currently under evaluation include psoralen plus ultraviolet light A, MMF, thalidomide, total lymphoid irradiation, Plaquenil, extracorporeal photopheresis, pentostatin, and acetretin.[344] (Table 109-4 lists the commonly used GVHD drugs and their side effects.)

Table 109-5 National Institutes of Health Chronic Graft-Versus-Host Disease Measures

Measure	Clinician-Assessed	Patient-Reported
CHRONIC GVHD-SPECIFIC CORE MEASURES		
Signs	Organ-specific measures	Not applicable
Symptoms	Clinician-assessed symptoms	Patient-reported symptoms
Global rating	Mild, moderate, or severe 0 to 10 severity scale 7-point change scale	Mild, moderate, or severe 0 to 10 severity scale 7-point change scale
CHRONIC GVHD NONSPECIFIC ANCILLARY MEASURES		
Function	Grip strength 2-minute walk time	Patient-reported function
Quality of life	—	Patient-reported health-related quality of life

SYNGENEIC GRAFT-VERSUS-HOST DISEASE

A GVHD-like syndrome that is usually self-limited and predominantly affects the skin can occur in recipients of syngeneic or autologous transplants.[369] It is also possible that some of the reported cases of syngeneic GVHD have reflected a mistaken assumption that the donor was syngeneic without extensive molecular confirmation. The condition manifests primarily as a rash that usually responds promptly to corticosteroid therapy. Although the level of severity may be grade II or III, the disease generally resolves promptly with the administration of glucocorticoids and is not life-threatening. Virtually all patients in whom a GVHD-like syndrome develops after syngeneic transplantation have been prepared with intensive conditioning regimens, usually involving irradiation. Experimental studies suggest that such conditioning is essential for the induction of thymic dysfunction, which is necessary for the development of the disease. Generation of autoreactive cells (a defect in thymic negative selection) and elimination of regulatory cells appear to be the requirements for the development of this disease. An additional hypothesis is that in some individuals maternal cells transmitted to them during their fetal development remain present throughout adult life.[370] These observations suggest the possibility that in some instances small numbers of HLA-incompatible cells (derived from the donor's mother) may be transmitted with HLA-identical transplants. Transplacentally transferred maternal cells may also play a role in the development of neonatal GVHD.[370]

Transfusion-Associated Graft-Versus-Host Disease

Most blood products administered to immunocompromised patients are now irradiated or at least leukocyte-depleted to avoid the transfusion of viable alloreactive T cells. With most homologous blood products, the MHC incompatibility between donor and recipient results in rapid clearance of transfused T cells by the recipient's immune system. However, occasionally, transfusions from donors who are homozygous for one of the recipient's MHC haplotypes are not recognized as foreign by the recipient.[371-373] These cells can survive, "engraft," and mount an immunologic attack against the unshared haplotype in the patient, resulting in transfusion-induced GVHD.[373] Transfusion-associated GVHD differs from GVHD occurring after transplantation in terms of kinetics and manifestations (i.e., with transfusion-associated GVHD, the recipient marrow is a major target).[372] Since the number of stem cells in the offending blood product is inadequate, there is no hemopoietic recovery from donor cells. This syndrome is generally fatal as a result of refractory pancytopenia and/or other organ involvement.

GRAFT-VERSUS-LEUKEMIA RESPONSES

The GVL response after allogeneic HCT results from the immunologic attack of the host tissue and, by extension, the leukemia (i.e., the tumor). This response represents a potent form of immunotherapy that circumvents some of the "immunoediting" mechanisms used by tumor cells to develop in the hosts. The power of the alloimmune response to eliminate malignancy was first reported more than 50 years ago in experimental models by Barnes et al.[1] However, GVL as its own entity and its close association with GVHD were not established until another 15 years later.[374]

Clinical Features

Clinical evidence that the donor graft mediates important antileukemic effect comes from higher relapse rates for recipients of syngeneic stem cells than for recipients of HLA-matched sibling grafts.[375] These findings have also been confirmed in a multicenter analysis of HCT recipients with acute myelogenous leukemia (AML) in first remission

and subsequent retrospective analyses by the International Bone Marrow Transplant Registry (IBMTR).[376-378] The second IBMTR analysis also showed that the magnitude of this GVL effect is greater for patients with CML and AML and not statistically significant for patients with acute lymphoblastic leukemia (ALL) in first remission.[379,380]

Several case reports of patients with relapse of leukemia after allogeneic HCT noted remissions of the malignancy either after abrupt withdrawal of immunosuppression or during a flare of acute GVHD.[381-384] Patients who develop GVHD after allogeneic HCT experience relapse less frequently than similar patients who do not develop clinical disease. GVHD is protective against relapse both for HCT recipients with advanced leukemia[385-387] and for patients who receive transplants in earlier stages of malignancy.[388] Additional analyses also suggest that the magnitude of the GVL effect appears to be disease- and stage-specific.[387-389] Initial reports suggested that chronic GVHD was most protective against relapse,[387] but other analyses demonstrate that acute GVHD is also protective.[388] Based on these reports, newer trials of immunotherapy are designed to include cessation of immunosuppressive therapy (without taper) to induce a GVL reaction for patients whose malignancy has relapsed after HCT. Furthermore, Childs and colleagues demonstrated that the graft-versus-tumor effect also plays an important role in inducing remissions from a nonhematologic malignancy, renal cell carcinoma.[390]

Another line of clinical evidence regarding the GVL effect of allogeneic HCT and its tight linkage to GVHD comes from the studies employing T-cell depletion of the donor graft. Donor T cells included in the stem cell graft are critical for acute GVHD, and T-cell depletion by various strategies is one of the most successful means of reducing the incidence and severity of GVHD after allogeneic HCT.[27,391-396] Unfortunately, although T-cell depletion results in less treatment-related morbidity and mortality, improved overall survival rates have not been reliably demonstrated. This failure is due in large part to a reciprocal increase in the subsequent relapse rate after T-cell depletion, as well as to graft failure and other complications.[389,397,398] T-cell depletion increases relapse rates particularly in CML.[388,389,399] This observation provides further strong, albeit indirect, evidence that allogeneic donor T cells are important mediators not only of GVHD, but also of the GVL properties of the allogeneic stem cell graft. Finally, the most compelling evidence of donor T cells in mediating GVL comes from the observations made from donor lymphocyte infusions (discussed later). The induction of GVL is a complex process.

Genetic Basis

The immunotherapeutic effect that occurs in allo-BMT setting is primarily mediated by allogeneic donor T or NK cells directed against the alloantigens shared by the recipient tumor and target tissues and/or tumor-specific antigens that have the advantage of not being subjected to tolerance mechanisms by the host tumor.[56,400,401] Understanding of the exquisite specificity of T cell responses led to attempts to identify specific antigens that are responsible for the GVL effect. Much of the focus has been on the identification of (1) certain oncogenic viral proteins (because these are absent in normal cells but expressed by transformed tumor cells [certain EBV peptides such as EBNA-1, LMP-1, LMP, LCL]), (2) antigens that are expressed in a tissue-specific fashion (melanoma specific proteins), and (3) proteins that are overexpressed in tumors (WT1, proteinase 3, survivin, telomerase reverse transcriptase, CYPB1, and HER2/neu).[53,56] Although these antigens are specific, most T-cell responses to these antigens are limited because of the poor immunogenicity of these proteins, expression on normal cells, defects in the processing or presentation of tumor antigens, or production of factors that disable T-cell responses. Thus clinical attempts to obtain high specificity of T-cell responses have been offset with difficulties in obtaining enough sensitivity and vice versa. Furthermore, given the current concepts of stem cell origins of leukemia and cancers, identification of the immunogenic proteins that are specifically expressed in the malignant stem cells and harnessing T cell responses to those antigens will be needed for the optimal GVL effect to cure malignancy.[402,403]

In contrast to the tumor-specific or tumor-associated antigens discussed earlier, alloantigens are not subjected to tolerance mechanisms. Vaccination strategies with autologous T cells using tumor-associated or tumor-specific antigens have yielded disappointing clinical antitumor responses.[404] By contrast, allogeneic HCT has met with remarkable GVL responses perhaps owing to recognition of minor alloantigens in addition to the tumor-associated antigens.[405] This concept has been demonstrated by recent murine studies, which showed that alloantigen on the tumor cells is required for GVL responses and that the principal targets of GVL are the immunodominant allogeneic MiHAs rather than the tumor-associated antigens.[60,90] Thus T cells specific for MiHA antigens could provide for a potent GVL effect. Significant progress has been made in the identification of MiHAs that are specifically expressed in the host hematopoietic tissues and therefore might allow for a GVL response without causing GVHD.[53] Together, these results suggest that in addition to tumor-specific proteins, expression of alloantigens and cognate interactions between donor T cells and the tumor tissues are required for the effective induction of the majority of GVL responses. However, T cells specific for some MiHAs are also responsible for GVHD, and a means of consistently separating the beneficial GVL effect from GVHD has not yet been clinically achieved.

KIR Polymorphisms

The two competing models described earlier, the "mismatched ligand" and the "missing ligand" models for HLA-KIR allorecognition, have been supported by clinical observations of GVL responses in different patient and transplant populations.[65,66] The former model has been shown to separate GVL and GVHD responses in the context of TCD haploidentical HCT for AML.[46,67] Even though this model is supported by elegant laboratory studies, it was found to be invalid for ALL and also for AML after unrelated donor HCT with immunosuppression.[67] Recent retrospective clinical data suggest that GVHD and GVL can be separated by the "missing ligand" model in CML/AML and MDS patients after TCD HLA identical sibling HCT.[46,66,69] Further validation of either models by clinical prospective studies and a better understanding of the balance between the inhibitory and activating receptor-ligand interaction of the NK cells are needed to adequately exploit the interface between HLA-KIR genetics to separate GVHD from GVL (see Chapter 102).[64,406]

Immunobiology of Graft-Versus-Leukemia Responses

Given the tight association of clinical GVHD and GVL, as well as the common biologic principles governing these responses after allogeneic HCT, it is important to discuss the similarities and distinctions between them in the context of the three cellular phases of GVHD.[407]

Phase 1: Activation of APCs

The concept that tumor eradication after allogeneic HCT might not require toxic chemoradiotherapy and could be achieved primarily by the immunotherapeutic effect from the GVL responses has led to the clinical development of nonmyeloablative HCT for hematologic and nonhematologic malignancies.[408] Phase 1 is characterized by the development of cytokine storm–generated danger signals from the conditioning regimen and the subsequent activation of APCs.[407] Experimental data suggested that the reduction in conditioning would attenuate the cytokine storm, lead to the development of mixed donor-host chimerism, and confine the GVH response primarily to secondary lymphoid organs, thus cause less severe GVHD without impairing GVL responses.[409-411] However, nonmyeloablative HCT has delayed the kinetics but did not reduce the overall incidence

of GVHD and a significant number of patients either failed to respond or relapsed.[22] Furthermore, recent murine and human studies have suggested that homeostatic expansion of T cells in a lymphopenic environment induced by conditioning (as opposed to mere immunosuppression) improves the antitumor efficacy of adoptively transferred syngeneic or autologous T cells by increasing the availability of space, enhancing the memory responses, and reducing the competition for homeostatic cytokines (such as IL-7 and IL-15) for transferred T cells while eliminating regulatory T cells.[412-414] Thus low-intensity HCT clearly demonstrates the principle of GVL effect, but the roles of cytokine storm and homeostatic expansion of allogeneic T cells in shaping the intensity of GVL responses are not known.

Host and donor APCs are critical for the induction and severity of GVHD.[8] Activation of APCs is the key step in phase 1 of GVHD.[407] Significant progress has been made in understanding the role of APCs in GVL. Recent experimental evidence has demonstrated a crucial role for professional host APCs in the induction of GVL responses mediated by donor T cells, even when the tumor cells showed some features of APCs.[90,415] Tumors that merely express costimulatory molecules may still be unable to stimulate an effective immune response because of their various "immunoediting" processes that cause ineffective antigen presentation.[416] However, when the tumor cell itself functions as a professional APC, as with CML, it can generate an effective GVL response.[417,418] By contrast, cancers such as acute leukemias that seldom differentiate into APCs generate poor GVL responses. Data also demonstrated that given sufficient time and a low tumor burden, cross-presentation of tumor-associated antigens and/or alloantigens by professional donor APCs can occur and may promote or sustain GVL responses by maintaining or expanding alloreactive T cells after initial priming on host APCs.[90,418] This concept is consistent with clinical GVL responses in CML in which the final stage of a GVL response to CML may be the result of donor T cells responding not directly to the small number of CML stem cells or progenitors (which would be undifferentiated and therefore poor APCs) but to tumor antigens cross-presented on professional donor APCs. Emerging data suggest that enhancing such cross-presentation is sufficient to elicit effective GVL responses against acute or advanced leukemia. These data, however, suggest that GVL responses generated after low intensity conditioning may not be as robust as those after full intensity HCT and highlight the need for a clearer understanding of the effects of cytokine storm and lymphopenia generated danger signals on the activation of APCs in mediating GVL.

Phase 2: Donor T Cell Activation

The core of GVL responses, as with GVHD, is also dependent on the activation of appropriate numbers of T cells. The "second" signals from professional APCs (or certain tumor cells that function as effective APCs) are critical for generating an effective GVL response.[230] Several of the costimulatory pathways that modulate GVHD have also been evaluated in mediating GVL responses. Blockade of CD28 costimulation preserved GVL responses but reduced GVHD in murine studies.[419] However, when the tumor cells also expressed B7 molecules, such blockade reduced the GVL responses.[417] Ex vivo blockade of CD40-CD40L interaction has been shown to reduce GVHD by generating Tregs but still preserve GVL. By contrast, blockade of the 4-1BB pathway reduced both GVHD and GVL.[123] The other costimulatory molecules (OX40 and ICOS) and the inhibitory molecules (CTLA-4 and PD-1) also modulate antitumor responses.[124,125] A better understanding of the context (i.e., low intensity or DLI) and the hierarchy of timing, duration, and extent of costimulatory requirements of donor T cell subsets might allow for balancing the intensity of GVL and GVHD responses. Clinical and experimental evidence suggest that donor T cell numbers correlate with the severity of GVHD and GVL responses. T cell–depleted (TCD) grafts had reduced GVHD but increased disease relapse, suggesting a role for T-cell numbers in GVL responses as well.[420] Clinical attempts to separate GVHD and GVL by regulating allogeneic T-cell dose have met with limited success. For example, administration of 1×10^5 T cells/kg after HLA-matched sibling transplantation did not mediate GVL effects and yet was associated with a measurable incidence of GVHD. Thus infusion of right numbers of donor T cell effectors is crucial for GVL responses.[420] This has been demonstrated by durable responses that are observed in CML and other malignancies after donor leukocyte infusion (DLI, see later), despite the experimental evidence that host APCs stimulate a stronger GVL response than do donor APCs.[90,418] This could be because, clinically, DLI is almost always given without immunosuppression to an individual who has not developed GVHD either from the chemical immunosuppression or physical removal of donor T cells from the allograft. This lack of immunosuppression after DLI increases the likelihood of a GVH response, and DLI is almost always associated with clinical GVHD. The delivery of additional allogeneic effector cells in DLI also increases the effector: target ratio compared with the time of initial HCT. The latter is also clinically demonstrated by a more effective GVL response to DLI against minimal residual disease (BCR-ABL positivity by PCR) compared with the response against high leukemic burden (e.g., blast crisis) in CML patients.[418] Thus DLI provides the proof in principle for the concepts that sufficient T-cell numbers and appropriate antigen presentation are required for both GVHD and an effective GVL response.

T-Cell Subsets

Most experimental studies have implicated donor $CD8^+$ T cells as the primary mediators of GVL, but there are no clinical data for $CD8^+$-mediated GVL responses in the absence of CD4 T cells.[56,236,418] Moreover, some clinical data suggest a role for greater CD4-mediated GVL responses without an increase in GVHD after allogeneic HCT and DLI.[415,421-424] But it is unclear whether $CD4^+$ T cell–initiated GVL responses occur in the absence of generation of MiHA specific $CD8^+$ T cells. Given the critical requirement of alloantigens for most GVL responses, the specific requirement of CD4 and/or CD8 T cells for GVL and GVHD is likely to be determined by the expression of the relevant immunodominant MiHAs and/or tumor-associated proteins. Therefore it is unlikely that GVHD and GVL responses can be separated under all circumstances merely by depletion of either subset of alloreactive T cells. However, experimental data suggest it might be possible to separate GVHD and GVL when certain donor T-cell subsets are either depleted or infused (DLI) at appropriate interval after transplant.[415] But the optimal time interval, if any, after clinical HCT is yet to be determined.

Because of recent identification and understanding of the role of various T-cell subsets in mediating immune responses, depletion of specific T-cell subsets to separate GVHD and GVL remains an area of active investigation. For example, recent experimental data suggest that CD62L expressing naive T cells home to secondary lymph nodes and are critical for initiating GVHD.[133] By contrast, CD62L negative effector memory T cells with enhanced reactivity to recall antigens mediated GVL responses with minimal GVHD.[133] An important caveat to these data is the fact that the lack of a priori knowledge of the repertoire of human memory T cells would make it difficult to predict whether these cells might cross-react only with tumor-associated antigens or with the recipient's alloantigens. Using CD62L status alone as determinant of GVHD potential can also have other unintended consequences; recent studies have demonstrated that its expression is critical for the regulation of GVHD by Tregs (see later). Moreover, it is not known whether the behavior of human memory T cells parallels that of murine memory T cells in their migratory, functional, and cytolytic capabilities. Although Tregs reduce antitumor immunity in murine models and in human subjects experimental data suggest that administration of donor-type Tregs either at the time of HCT or when delayed reduced GVHD but preserved $CD8^+$-mediated perforin-dependent GVL responses.[425,426] Similar preservation of experimental GVL was also observed by harnessing donor NKT function with GCSF analogues.[159,160] However, it remains unclear whether these observations are valid after clinical HCT when the GVL responses might not be entirely dependent on CD8 T cells.

T-Cell Migration

It is conceivable that manipulation of these interactions to focus the alloimmune response to lymphohematopoietic tissues would enhance GVL responses but not GVHD. For example, blockade of CCR9 ligand TECK or CCR5 and CCL17 may prevent the migration of donor T cells to GI tract and skin respectively, but preserve GVL.[221] Pharmacologic manipulation with the immunosuppressive agent FTY720 has recently provided the proof in principle for this approach.[231] Given the redundancy, strategies to modulate the chemokine biology for separation of GVHD and GVL will require greater understanding of these networks in modulating the migration not only of specific T-cell subsets but also of the other immune cells in the context of different conditioning regimens.

Phase 3: Effector Phase of GVL

The effector arm of GVL is also characterized primarily by the antigen-specific cellular components and less by the inflammatory components of alloresponse. Experimental data demonstrate that neutralization of IL-1α reduced GVHD but preserved GVL.[283] By contrast, donor TNF-α secretion contributes to both GVHD and GVL effects, and in some cases, antagonism of TNF-α reduced GVHD and GVL responses.[427-429] Nonetheless, antagonism of nonspecific inflammatory effectors (such as either IL-1 or TNF-α) appears to regulate GVHD to a greater extent than GVL responses after experimental allogeneic HCT.[429]

Several lines of experimental and clinical data demonstrate that antigen-specific donor T-cell subsets and NK cells are the key effectors of GVL.[56] The cytotoxic pathways that are operative in the NK and T cell–mediated antitumor responses have been well characterized.[56] Fas ligand–mediated CTL of tumor targets is used by both NK and T (mostly Th1) cells, but most murine experiments with FasL-deficient donor T cells suggested that FasL is a key effector molecule for causing GVHD but not GVL.[236] However, one study found that FasL is required for $CD4^+$–mediated GVL against myeloid leukemia.[430,431] By contrast, even though perforin-mediated CTL pathways are also used by T (mostly Th2) and NK cells, experimental data with perforin-deficient donor T cells demonstrated a loss of GVL with a diminution in the severity of GVHD.[236] In some other experimental models, perforin was required only for GVL but not for GVHD.[236] Recent data showed that TRAIL-mediated CTL had no effect on GVHD severity but was required for optimal GVL.[260] Therefore strategies that increase donor T cell TRAIL expression or enhance the susceptibility of tumors to TRAIL-mediated CTL (such as HDAC inhibitors) may promote a robust GVL effect without exacerbating GVHD.[432-434] Thus a significant progress has been made in recent understanding of the CTL pathways employed by donor T cells for GVL responses, but the role and context of use of these pathways by donor NK and NKT cells after allogeneic HCT are not known.

DONOR LEUKOCYTE INFUSIONS

Until recently, the evidence for an important GVL effect in clinical transplantation was strong but largely circumstantial. The use of DLI to treat relapses after allogeneic HCT has now provided direct evidence of the GVL effect.[435-437] Kolb and colleagues first reported three patients with relapsed CML who achieved complete cytogenetic remission after treatment with IFN-α and DLI from the original donors.[438] Subsequently, these findings have been confirmed in several reports.[439-441] Two large retrospective studies of DLI have been reported from Europe and North America.[437,442] Although the treatment protocols varied slightly among institutions, the results have been remarkably consistent. When results from these trials are combined, the complete remission rate for patients treated for relapsed CML is consistently 60% to 80%.[435] In many patients with CML, the response to DLI is not immediate. The average time to obtain a molecular remission is between 4 to 6 months, but disease free survival after DLI depends on the stage of CML.[443,444] Complete cytogenetic and molecular responses are achieved in almost 80% of patients treated with either early relapse (cytogenetic or molecular) or hematologic relapse of chronic phase.[380] Patients with more advanced CML (accelerated phase or blast crisis) are less likely to respond. Two recent analyses suggest that the outcome after unrelated DLI is similar to matched sibling DLI in CML patients.[437,442]

DLI has also produced remissions in acute leukemias. Several retrospective studies have reported response rates in AML ranging from 20% to 65%.[380,442,445-447] A prospective study of 65 patients with advanced myeloid leukemia who received cytarabine and GCSF-primed DLI showed that 47% of the patients achieved complete remission, with an overall survival of 19% at 2 years.[448] A recent EBMT analysis of DLI in patients with relapsed AML showed a response rate of 41%, which did not change if chemotherapy was used before DLI.[449] Generally, DLI produces lower response rates and higher relapse rates in patients with AML than in those with CML.[380,418,442,445-447] Extramedullary relapses at multiple regions that are usually not considered sanctuary sites for leukemia have been observed after DLI.[447]

Although GVL responses to ALL after allogeneic HCT have been noted, DLI for ALL has generally been ineffective.[399] Reports both from Europe and the United States found little benefit for DLI in ALL patients.[418,442,445,446] Furthermore, Ruggeri and others found that following TCD haploidentical HCT where the donors had antirecipient NK cells, the probability of relapse was 85% for ALL in contrast with 0% for AML.[67,450]

The experience with DLI for other hematologic malignancies such as NHL and multiple myeloma (MM) is much more limited. Case reports and small series demonstrate responses to DLI in patients with posttransplant relapses of low-grade lymphoma and CLL and also after low-intensity HCT.[451,452] In MM, complete responses to DLI were observed in 25% of the patients in two small series.[418,453,454] DLI has also been shown to induce complete remission in a majority of patients with posttransplant lymphoproliferative disorders (PTLD) after allogeneic HCT.[439,455] Viral infections may be treatable with DLI, and adoptive immune therapy with T cells specific for EBV and CMV have been shown to both treat and prevent these complications.[456-460]

Complications of Donor Leukocyte Infusions

Adoptive immunotherapy with DLI causes significant morbidity. The major complications are myelosuppression and GVHD. Myelosuppression with anemia and/or thrombocytopenia and/or leucopenia and/or pancytopenia occurs in 34% of the patients.[444] Marrow aplasia presumably results from the destruction of host leukemia cells before recovery of normal donor hematopoiesis. This idea is supported by the observation that patients treated with donor MNC infusions for cytogenetic or molecular relapse rarely experience pancytopenia.[437] Occasionally, marrow aplasia has been persistent,[439,440,461] although this toxicity has been successfully reversed with the infusion of additional donor stem cells in some patients.[439,440] If pancytopenia is associated with chronic GVHD, then immunosuppression might be the most appropriate therapy.[462] Acute GVHD and chronic GVHD have been the major direct complications from DLI. In retrospective and prospective studies, acute or chronic GVHD has been reported in 40% to 60% of evaluable patients. In most studies, GVHD correlates with GVL activity and response.[437,442] In the North American analysis, over 90% of complete responders developed acute GVHD, and 88% of responders developed chronic GVHD. Of 23 patients who did not experience GVHD, only 3 achieved a complete remission. In 92 patients who had no response, only 35% had acute GHVD and only 13% had chronic GVHD. In the EBMT analysis, 41% of DLI recipients developed grade II to IV acute GVHD.[437] It should be noted, however, that many patients who fail to respond to GVL induction will die shortly of progressive disease and may not survive long enough for GVHD to develop. This is particularly important for patients with acute leukemia. It is also important to emphasize that a number of complete responses were seen in patients

without any sign of GVHD. The GVL effect in the absence of clinical GVHD provides important evidence for GVL activity separate from GVHD.

In general, GVHD that occurs after DLI has been mild to moderate and has been responsive to immunosuppressive therapy. This observation is important since the dose of T cells often administered with DLI may be 10- to 100-fold higher than the T-cell dose administered at the time of transplant, and DLI is given without additional immunosuppression. At the time of transplant, toxicity is unacceptable if immunosuppression is withheld or if a dose of donor T cells similar to that used for DLI is given (to augment GVL).[463,464] This may be because the effects of GVHD are more tolerable when separated from the acute transplant toxicity. GVHD can be stimulated and exacerbated by the cytokine storm that may accompany transplantation. Tissue damage from the intensive conditioning regimen, infections, and other physiologic insults results in a cascade of events that ultimately augments the GVHD reaction.[23] When GVHD is induced independently of other transplant related toxicity, it may be more manageable with appropriate immunosuppression. Nevertheless, in some cases DLI-induced GVHD may be quite severe; as shown in Table 109-2, 20% to 35% of DLI recipients can be anticipated to develop grade III or IV acute GVHD. Furthermore, acute GVHD has contributed to death in almost 10% of patients.[465] Chronic GVHD occurs in 30% to 60% of recipients of unmanipulated DLI.

It is notable that the clinical presentation of GVHD after DLI is somewhat different from that after myeloablative allogeneic HCT. For instance, the onset of GVHD may be later after DLI. The median time to onset of acute GVHD is approximately 32 to 42 days[442,466] compared with a median time to onset of 16 to 20 days following myeloablative T cell–replete transplantation.[305,467] Therefore not only can the severity of GVHD be influenced by the use of intensive conditioning, but the tissue damage and inflammatory cytokine release may influence the pace of GVHD development as well. This possibility is supported by the finding that time to onset of acute GVHD is also delayed following reduced intensity transplantation.[468] The target organs of acute GVHD following DLI are the same as those seen following HCT, but the clinical manifestations may differ. A hepatic variant of liver GVHD characterized by marked elevations of serum aminotransferase levels more than 10 times the upper limit of normal was observed in 11 of 73 (15%) patients who received DLI at Johns Hopkins University.[318] Characteristic skin, liver, and intestinal acute GVHD manifestations can be seen following DLI, but their frequency and severity has not been well described. In a study of 81 patients who received DLI for relapse, mixed chimerism, or prophylaxis following reduced-intensity HCT, skin, liver, and intestinal GVHD developed in 26%, 8%, and 14%, respectively.[469] Likewise, characteristic findings of chronic GVHD can be seen following DLI,[469] and on occasion both acute and chronic GVHD can develop simultaneously following DLI.[470]

In recent years, DLI has been used in the context of reduced-intensity allogeneic HCT. When conditioning is minimal and GVHD has not already occurred, DLI is often required to either reverse mixed chimerism or treat persistent disease.[469,471,472] GVHD after DLI following nonmyeloablative setting develops 19% to 45% of the time, whereas chronic GVHD develops 28% to 34% of the time. In two studies of a combined 134 subjects who received DLI after reduced-intensity transplantation, 37 (28%) patients developed acute GVHD, 15 (11%) developed grade III or IV GVHD, and 8 (6%) died from GVHD.[469,471] There was no statistically significant relationship between DLI dose and GVHD in either study. The clinical features of GVHD after DLI following reduced-intensity HCT are similar to the GVHD that occurs after DLI is used to treat relapse following myeloablative HCT. The similarity between GVHD after DLI in either setting suggests that the reduction of tissue damage associated with either no chemotherapy (as in DLI for relapse following prior myeloablative HCT) or reduced-dose chemotherapy (as in DLI after reduced-intensity HCT) may be an important common theme.

It is likely that effector cells responsible for the GVL and GVHD effects of HCT will similarly be responsible for the GVL effect associated with DLI, although this assumption has not been formally proven. The administration of select subsets of donor mononuclear cell fractions is the ideal setting in which to dissect the cellular mechanisms responsible for GVL induction, and strategies that delay the infusion of these various cellular subsets will help define the mechanisms and enhance the efficacy of DLI.

FUTURE DIRECTIONS

Complications of HCT, particularly GVHD, remain major barriers to the wider application of allogeneic HCT for a variety of diseases. Recent advances in the biology of genetic polymorphisms, the chemocytokine networks, several novel cellular subsets including regulatory T cells, and the direct mediators of cellular cytotoxicity have led to improved understanding of this complex disease process. Animal studies show that modulation of several mediators of the complex GVHD cascade may be able to reduce the undesirable inflammatory aspects of GVHD while preserving the benefits of GVL. However, most of the laboratory observations remain to be studied in well-controlled clinical trials. Multiple cellular effectors may be involved in GVL, although donor T-cell recognition of host antigens is an important element of this process. Cellular immunotherapy such as DLI offers a strategy for separating GVHD and the GVL effect. Both experimental and clinical data suggest that posttransplantation cellular immunotherapy can be performed relatively safely and effectively, and optimization of patient selection, cell dose, and timing of administration may all serve to limit toxicity and enhance the potential GVL effects.
